

## INFORMATION TO USERS

This manuscript has been reproduced from the microfilm master. UMI films the text directly from the original or copy submitted. Thus, some thesis and dissertation copies are in typewriter face, while others may be from any type of computer printer.

**The quality of this reproduction is dependent upon the quality of the copy submitted.** Broken or indistinct print, colored or poor quality illustrations and photographs, print bleedthrough, substandard margins, and improper alignment can adversely affect reproduction.

In the unlikely event that the author did not send UMI a complete manuscript and there are missing pages, these will be noted. Also, if unauthorized copyright material had to be removed, a note will indicate the deletion.

Oversize materials (e.g., maps, drawings, charts) are reproduced by sectioning the original, beginning at the upper left-hand corner and continuing from left to right in equal sections with small overlaps. Each original is also photographed in one exposure and is included in reduced form at the back of the book.

Photographs included in the original manuscript have been reproduced xerographically in this copy. Higher quality 6" x 9" black and white photographic prints are available for any photographs or illustrations appearing in this copy for an additional charge. Contact UMI directly to order.

## **Acknowledgments**

I am grateful to Dr. Gary Rochelle for his guidance and support in doing this work. I never cease to be amazed by his quick perception of concepts and his ability to intuitively analyze complex problems. I also appreciate the assistance of my committee members, Professors Roger Bonnecaze, Matthew Hall, William Koros and Howard Liljestr nd.

I wish to acknowledge the Electric Power Research Institute (EPRI) for their financial support under contract number RP 3470-02.

My parents have been a lasting inspiring since I was a little girl. They support every decision I made to achieve great things in my life. This was certainly one of them.

Finally, I want to thank my husband, Bin, for his continuous love and support. He is an excellent husband and friend and I am very lucky to have him in my life.

## **Mercury Absorption in Aqueous Solutions**

Publication No. \_\_\_\_\_

Lingbing Zhao, Ph.D.

The University of Texas at Austin, 1997

Supervisor: Gary T. Rochelle

The absorption of elemental Hg vapor into various aqueous solutions was measured in a stirred cell contactor at 25°C and 55°C. The gas film mass transfer coefficient was measured using concentrated acidic permanganate solution. The liquid film mass transfer coefficient was obtained by mercury desorption from HgCl<sub>2</sub> injected into acidic stannous chloride solution.

Acidic permanganate strongly absorbs mercury with overall second order kinetics. NaOCl strongly absorbs Hg even at high pH. Low pH, high Cl<sup>-</sup> and high temperature favor mercury absorption. Aqueous free Cl<sub>2</sub> was the active species that reacted with mercury. However, chlorine desorption was evident at high Cl<sup>-</sup> and pH < 9. A fast gas phase reaction occurred between Hg<sup>0</sup> and Cl<sub>2</sub> at room temperature. Cl<sub>2</sub> concentration, moisture, and solid surface area contributed positively to mercury removal.

Aqueous solutions containing Hg(II) also absorb Hg°. The addition of strong acids, such as HNO<sub>3</sub> or H<sub>2</sub>SO<sub>4</sub>, greatly enhanced Hg° absorption in Hg(II). However, HCl inhibited Hg° absorption in Hg(II).

Succinic acid-NaOH buffer solution greatly enhanced Hg° absorption in Hg(II) but NaHCO<sub>3</sub>-NaOH inhibited Hg absorption. Under most conditions, oxygen in the gas phase did not have any effect on Hg° absorption in Hg(II). However, oxygen had a positive effect on Hg absorption in Hg(II) when HCl or NaHCO<sub>3</sub>-NaOH was present in the solution.

The addition of MnSO<sub>4</sub> to Hg(II) only slightly enhanced Hg absorption while NaCl, MgSO<sub>4</sub>, FeCl<sub>3</sub>, CaCl<sub>2</sub> and MgCl<sub>2</sub> all inhibited Hg absorption in Hg(II).

Hg° absorption in Hg(II) was further enhanced by adding oxidants. The addition of H<sub>2</sub>O<sub>2</sub> to HNO<sub>3</sub> gave the most Hg° removal. Both K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> and K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>-HNO<sub>3</sub> enhanced Hg° absorption in Hg(II) and the positive effect of adding HNO<sub>3</sub> was more apparent than that of adding K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>. At 10<sup>-5</sup> M Hg(II), 0.26 M H<sub>2</sub>O<sub>2</sub>-0.8M HNO<sub>3</sub> gave the most mercury removal, followed by 0.03 M K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>-0.8 M HNO<sub>3</sub>, and then 0.1 or 0.8 M HNO<sub>3</sub>, or 0.8 M H<sub>2</sub>SO<sub>4</sub>.

Solutions typical of limestone slurry did not remove Hg°. Sodium sulfite and sodium thiosulfate were the main species tested in this research. Other typical limestone slurry additives, such as succinic acid, FeSO<sub>4</sub>, CaCl<sub>2</sub>, MnSO<sub>4</sub>, MgSO<sub>4</sub>, and MgCl<sub>2</sub>, did not make any difference when sulfite and/or thiosulfate were present in the solution.

Aqueous sodium sulfide and aqueous polysulfide were not effective for Hg° absorption.

## Table of Contents

List of Tables .....	ix
List of Figures .....	xii
Chapter 1 Introduction .....	1
1.1 Mercury and Pollution .....	1
1.2 Research Objective .....	4
Chapter 2 Literature Review .....	8
2.1 Understanding Mercury .....	8
2.1.1 Physical-Chemical Properties .....	9
2.1.2 Transportation and Fate of Mercury Emissions.....	10
2.1.3 Characteristics of Mercury in Flue Gases .....	10
2.1.4 The Question of Permanent Capture and Ultimate Disposal .....	12
2.2 Control Technologies.....	13
2.2.1 Control the Mercury Content of the Fuel .....	13
2.2.2 Particulate Control Devices .....	14
2.2.2.1 Electrostatic Precipitator (ESP) .....	14
2.2.2.2 Fabric Filter .....	15
2.2.3 Wet Scrubbing .....	15
2.2.4 Spray-Dryer Scrubbing .....	17
2.2.5 Modified Mercury Control Processes .....	17
2.3 Mercury Emission Standards .....	19
2.3.1 Coal-Fired Power Plants .....	19
2.3.2 Municipal Waste Combustors.....	20
2.4 Theory of Simultaneous Mass Transfer with Chemical Reaction .....	20
2.4.1 Film Theory .....	20
2.4.2 Penetration Theory.....	21
2.4.3 Surface Renewal Theory.....	21
2.4.4 The Effects of Chemical Reactions .....	21

2.5	Aqueous Phase Reactions .....	24
2.5.1	Reduction of $\text{Hg}^{++}$ by Sulfite .....	24
2.5.2	Reaction between $\text{HgCl}_2$ and $\text{S}_2\text{O}_3^{=}$ .....	25
2.5.3	Oxidation of $\text{Hg}^\circ$ and $\text{Hg}^{++}$ by $\text{KMnO}_4\text{-H}_2\text{SO}_4$ .....	25
2.5.4	Oxidation of $\text{Hg}^\circ$ and Reduction of $\text{Hg}^{2+}$ by $\text{H}_2\text{O}_2$ .....	25
2.5.5	Oxidation of $\text{Hg}^\circ$ by $\text{Cl}_2$ , $\text{HOCl}$ and $\text{OCl}^-$ .....	26
2.5.6	Oxidation of $\text{Hg}^\circ$ by Ozone .....	27
2.5.7	Oxidation of $\text{Hg}^\circ$ by Organoperoxy Compounds .....	28
2.6	Gas Phase Reactions .....	28
2.7	Existing Problems .....	29
Chapter 3	Experimental Apparatus and Analytical Methods .....	31
3.1	Teflon Coated Stirred Tank Reactor .....	32
3.2	Elemental Mercury Source .....	35
3.3	Gas Phase Mercury Analysis .....	37
3.4	Liquid Phase Mercury Analysis .....	38
3.5	Typical Gas Flow Path and Experimental Operation .....	38
3.6	Minor Differences in Experimental Conditions and Operations .....	39
3.7	List of Instruments Used in the Research .....	40
Chapter 4	Calibration of the Apparatus .....	41
4.1	Mercury Analyzer Calibration .....	41
4.1.1	Analyzer Output Choice .....	41
4.1.2	Analyzer Drift and Linearity .....	42
4.1.3	Interferences for Mercury Analysis .....	44
4.1.4	Summary .....	46
4.2	Liquid Film Mass Transfer Coefficient .....	47
4.2.1	$\text{Hg}^\circ$ Desorption from Water without Reducing Agent at 25°C .....	47
4.2.2	$\text{Hg}^\circ$ Desorption from Water in the Presence of Reducing Agent at 25°C .....	50
4.2.2.1	Theoretical Basis .....	50
4.2.2.2	Experimental Procedure .....	50

4.2.2.3 Results and Discussion .....	51
4.2.3 CO <sub>2</sub> Desorption from Water at 25°C.....	53
4.2.4 Comparison of $k^o_{l, Hg}$ Obtained from Different Methods .....	56
4.2.5 Liquid Film Mass Transfer Coefficient of mercury, $k^o_{l, Hg}$ at 55°C .....	57
4.3 Gas Film Mass Transfer Coefficient Calibration.....	57
Chapter 5 Mercury Absorption in Aqueous Permanganate .....	58
5.1 Experimental Method .....	58
5.2 Mass Transfer with Simultaneous Chemical Reaction .....	61
5.3 Results and Discussion .....	62
Chapter 6 Mercury Absorption in Aqueous Oxidants Catalyzed by Mercury(II) .....	71
6.1 Previous Work .....	71
6.2 Experimental Methods .....	73
6.3 Determination of Mass Transfer Characteristics and Physical Properties of Mercury .....	75
6.4 Results and Discussion .....	76
6.4.1 Absorption in Mercury(II) .....	76
6.4.2 Absorption by Mercury (II) with the Addition of a Strong Acid or Buffer Solution .....	78
6.4.2.1 Mercury Absorption in 0.8 M Nitric Acid .....	79
6.4.2.2 Effects of HNO <sub>3</sub> , H <sub>2</sub> SO <sub>4</sub> and HCl.....	81
6.4.2.3 Effect of NaOH-succinic acid buffer .....	84
6.4.2.4 Effect of NaHCO <sub>3</sub> -NaOH buffer.....	84
6.4.3 Mercury Absorption in Hydrogen Peroxide and Nitric Acid ....	85
6.4.3.1 Hydrogen Peroxide and 0.8 M Nitric Acid.....	86
6.4.3.2 Effect of FeCl <sub>3</sub> in H <sub>2</sub> O <sub>2</sub> and HNO <sub>3</sub> .....	91
6.4.3.3 Effect of FeSO <sub>4</sub> in the presence of H <sub>2</sub> O <sub>2</sub> and HNO <sub>3</sub> ....	93
6.4.3.4 Effect of FeCl <sub>3</sub> or FeSO <sub>4</sub> with only H <sub>2</sub> O <sub>2</sub> present (no HNO <sub>3</sub> ) .....	94
6.4.4 Absorption in Mercury(II) and Potassium Dichromate .....	98
6.4.5 Mercury Absorption in Mercury(II) and Manganese(II) Sulfate .....	102

6.4.6 Effects of Negative Salts .....	103
6.4.6.1 The Effect of NaCl.....	104
6.4.6.2 The Effect of MgSO <sub>4</sub> .....	106
6.4.6.3 The Effect of FeCl <sub>3</sub> .....	106
6.4.6.4 The Effect of CaCl <sub>2</sub> .....	107
6.4.6.5 The Effect of MgCl <sub>2</sub> .....	108
6.4.7 Summary of Results.....	110
Chapter 7 Mercury Absorption in Aqueous Hypochlorite and Chlorine.....	114
7.1 Previous Work .....	114
7.1.1 Mercury Oxidation by Hypochlorite .....	114
7.1.2 Gas Phase Reaction of Mercury and Chlorine.....	115
7.2 Experimental Method .....	116
7.3 Mass Transfer with Simultaneous Chemical Reaction .....	117
7.4 Mercury Absorption in Sodium Hypochlorite .....	119
7.4.1 Effect of NaCl.....	122
7.4.2 Effect of pH .....	124
7.4.3 Effect of Temperature .....	130
7.4.4 Effect of HgCl <sub>2</sub> .....	131
7.4.5 Results with pH < 9 and Cl <sup>-</sup> ≥ 0.1 M.....	131
7.5 Gas Phase Reaction of Elemental Mercury and Chlorine .....	137
Chapter 8 Mercury Absorption in Simulated Limestone Slurry, Sulfide, and Polysulfide Solutions .....	141
8.1 Experimental Method .....	142
8.2 Simulated Limestone Slurry Scrubbing.....	144
8.2.1 Sulfite and/or Thiosulfate .....	145
8.2.1.1 Results with Injection-with-High-Gas-Flow-Rate .....	145
8.2.1.2 Results using Batch-with-Low-Gas-Flow-Rate.....	149
8.2.2 Effects of Additives .....	154
8.2.2.1 Results using the Injection-with-High-Gas-Flow-Rate .....	154
8.2.2.2 Results using Batch-with-Low-Gas-Flow-Rate.....	156

8.2.3 Succinic Acid or Succinic Acid/Sodium Hydroxide Mixture	156
8.3 Sodium Sulfide and Polysulfide	159
8.3.1 Results using Injection-with-High-Gas-Flow-Rate	159
8.3.2 Results using Batch-with-Low-Gas-Flow-Rate	160
Chapter 9 Conclusions and Recommendations	163
9.1 Conclusions	163
9.1.1 Strong Oxidants	163
9.1.2 Hg(II) without Oxidants	163
9.1.3 Hg(II) with Oxidants	164
9.1.4 Limestone Slurry Scrubbing, Na <sub>2</sub> S and Polysulfide Solutions	164
9.2 Recommendations for Further Work	165
Appendix A Safety Procedures in Handling Mercury	167
A.1 First Aid	167
A.2 Personal Protection	167
A.3 Spill, Leak and Disposal Procedures	168
Appendix B D <sub>Hg-H<sub>2</sub>O</sub> Estimation	169
Appendix C Results of Hg Absorption in KMnO <sub>4</sub> -1.8 M H <sub>2</sub> SO <sub>4</sub>	170
Appendix D Determination of H <sub>2</sub> O <sub>2</sub> by Iodometric Titration	171
Appendix E Results of Hg Absorption in Hg(II)-H <sub>2</sub> O <sub>2</sub> -0.8 M HNO <sub>3</sub>	172
Appendix F Determination of NaOCl by Iodometric Titration	174
Appendix G Hg Absorption in NaOCl-NaCl at Low and Intermediate pH	176
Appendix H Using $a_{\text{Cl}_2, \text{i}}$ for Hg Absorption in NaOCl at Low pH & 25°C	181
Glossary	183

## **Chapter 1 Introduction**

### **1.1 MERCURY AND POLLUTION**

Our community values the environment and clean air. Interest in controlling the emission of air toxic metals has intensified in the wake of passage of the 1990 Clean Air Act Amendments (CAAA). Among the eleven metals specified in the CAAA, mercury deserves the greatest attention both because of the emission rates and its potential hazard (Vogg et al., 1986).

Mercury is toxic to human because it acts primarily on the neurological system. Elemental mercury is actually relatively non-toxic. However, the divalent inorganic mercury compounds are considerably more toxic and organic methylmercury is more toxic yet by a factor of 10. While methylmercury is seldom present as an atmospheric emission from industrial processes, complex chemical reactions occur by which methylmercury is produced from elemental mercury or divalent mercury after they are deposited onto the soil or into lakes and streams. In lakes, methyl mercury is concentrated up the food chain so that large fish can have mercury concentrations in their flesh that is  $10^6$  times that in the surrounding water (Gilmour and Henry, 1991). Unacceptable levels of mercury are now even present in pristine areas of the upper Midwest and New England. Very serious problems have also been uncovered in Florida (Volland, 1991).

Mercury pollution of the environment has led to severe poisoning in several foreign countries as well as the United States (Slemr et al., 1985). To a

great extent the pollution with mercury has functioned as a trigger to the concern of the general public and of administration and industry of environmental pollution. This is particularly true for Japan, where epidemic intoxication with methyl mercury, due to contamination of sea food, occurred and caused the so called "Minamata Disease" (Takizawa, 1979). Following a severe drought that destroyed the wheat crop, Iraq imported seed grain which had been treated with a methylmercury fungicide. Many people mistakenly ate the seed which resulted in 450 deaths (Bakir et al., 1973). A Subsequent study estimated that a likely total of 5000 people died in this tragedy.

Even in other countries where no such catastrophe has occurred, mercury pollution is the issue which more than anything else has focused attention on pollution problems. The mercury problem is of general interest because it represents a pollution situation that we are likely repeatedly to encounter in the future in various parts of the world. Thus mercury pollution is of world-wide extent although the problems may not have been recognized everywhere yet (Ramel, 1973). The potential impact of fossil fuel combustion, in terms of the toxic metal emissions that can contribute to environmental pollution, is significant. At an estimated rate of coal combustion of  $700 \times 10^9$  kilograms per year in utility boilers in the United States (Smith, 1980), the yield of uncontrolled fly ash emissions would be approximately  $56 \times 10^9$  kilograms per year. For a trace element present in fossil fuel at a level of 1 part per million and assuming a 98 percent collection efficiency of the control device, the stack emissions would be about 1000 kilograms per year. If this element is mercury, where the collection efficiency of the control device is poor (Billing and Matson, 1972), and 98 percent

of the coal-bound mercury is emitted into the atmosphere, then the 1 part per million component would result in stack emissions of 55000 kilograms per year.

In January of 1990, a series of studies was completed addressing mercury contamination of lakes and streams in northern Minnesota (Swain, 1989). Researchers identified a three-fold increase in mercury deposition since the mid-1800's. Sorenson et al. (1989) concluded that airborne anthropogenic emissions are the chief cause, and most of the contamination appears to enter the lakes from wet deposition. Slemr and Langer (1992) have found that industrial pollution is causing mercury in the atmosphere to increase at a steady rate. Analyses of dated soil, peat bog and lake sediment records indicated that the total gaseous mercury has nearly doubled since the 1800's. The authors attributed more than 90 percent of the increase to human activities like coal burning, waste incineration and ore refinement. They said that although the current levels did not pose a health threat, they could become one by the mid-21st century if the increases continued at the current rate.

Mercury is generated from both natural and anthropogenic sources (Lindqvist et al., 1985). Degassing from mineral deposits, emissions from forest fires and volcanic eruptions, biological formation and photoreduction to produce elemental mercury from natural waters are examples of natural mercury sources (Hall et al., 1993). Energy production, waste incineration and smelting-refining are the major industrial processes that release mercury into the atmosphere. The total natural inputs of mercury to the atmosphere are  $5.4 \times 10^6$  pounds per year while those resulting from man's activities total  $7.8 \times 10^6$  pounds per year on a global scale (Nriagu et al., 1988).

Among man-made mercury emissions, energy production contributes 64% of the total amount and 33% is due to waste incineration (Nriagu et al., 1988). Since combustion of fossil fuels constitutes the primary means of energy production, combustion produces a significant portion of mercury emissions. Coal is one of the most commonly used fossil fuels. The concentration of mercury in coal varies from 0.01 to 8.0 ppm, depending on the type and the origin of the coal (Radian Corporation, 1989).

Since Congress approved the Clean Air Act in 1970 and Clean Air Act Amendment in 1990, over hundreds of billions of dollars have been invested in federal, state and local funds to assure a clean air and environment. Among these, public utilities alone comprised 35% of the all-industry total for air pollution control costs (Vatavuk, 1990). However, due to the limitations of current available technology, some of the air pollutants are still hard to remove from stack emissions. Mercury is among them. In fact, mercury is one of the most difficult species to remove due to its high volatility and low reactivity.

## **1.2 RESEARCH OBJECTIVE**

The specific objectives of this work were to quantify primary phenomena and major problems that may arise in the use of limestone slurry or other reagents for mercury emissions control from coal-fired power plants. Elemental mercury and mercuric chloride vapor are the two primarily forms of mercury emissions. Due to its high water solubility and relatively low vapor pressure ( $1.06 \times 10^6$  gmole/l-atm at 25°C, Clever, 1985), almost all of the mercuric chloride ( $\text{HgCl}_2$ ) is removed by conventional wet scrubber systems via physical absorption.

Elemental mercury, however, is unaffected in these systems because of its low solubility and high volatility (Wesnor, 1993; Noblett et al., 1993).

The most common Flue Gas Desulfurization system currently used in the industry is limestone slurry scrubbing. The major components of limestone slurry solution are sulfite and other aqueous cations and anions, such as  $\text{Ca}^{++}$ ,  $\text{Mg}^{++}$ ,  $\text{Na}^+$  and  $\text{Cl}^-$ , as shown in table 1.1. Our initial research objective was to assess the effect of limestone slurry scrubbing on mercury removal.

Table 1.1 Typical limestone slurry scrubbing solution composition.

Composition	Concentration (mM)
S(IV)	10
$\text{Ca}^{++}$	50
$\text{Mg}^{++}$	50
$\text{Cl}^-$	100
$\text{Na}^+$	20
pH	5-6

The limited solubility of elemental mercury vapor in water suggests that its absorption rate should be controlled by liquid film resistance. Any reasonable rate of mercury absorption will require that it be converted to more soluble products such as  $\text{Hg}^{2+}$  by reaction in the mass transfer boundary layer. Thus an aqueous oxidant is essential to the removal of mercury. If the solution itself is an oxidant, mercury removal would be accomplished by reacting with the oxidant. In limestone slurry scrubbing, the coexistence of reducing agents ( $\text{SO}_3^-$  and  $\text{S}_2\text{O}_3^-$ ) and possible oxidizing free radicals generated by sulfite oxidation (Owens, 1984) complicate the process. Even if elemental mercury is absorbed, the generated  $\text{Hg}^{2+}$  may be reduced back to elemental mercury by sulfite or other reducing agents in the mass transfer boundary layer or bulk solution. These

reactions would reduce total mercury removal by desorbing the produced elemental mercury. Desorption from reactions in the bulk solution would be limited by liquid film diffusion of mercury.

Based on above discussed reasons, limestone slurry scrubbing might not be effective for mercury removal. Other approaches, such as using aqueous oxidizing solution to absorb mercury, would be another scope of our research.

Previous investigators have reported substantial mercury removal in acidic permanganate solution (Monkman et al., 1956; Hara, 1975). EPA method 29 uses two impingers in series, with hydrogen peroxide and nitric acid in the first impinger and acidic permanganate in the second impinger, to speciate between elemental mercury and mercuric chloride vapor (Environmental Protection Agency, 1992). The effects of other strong oxidants on mercury removal, such as hypochlorite and potassium persulfate, have been reported elsewhere (Nene and Rane, 1981; Metzger and Braun, 1987). Although almost all of these previous works are qualitative in nature, it sheds light on the means to remove mercury. Despite the many differences in properties and oxidation potential of different oxidants, they seem to have one thing in common. Mercury was absorbed because it was oxidized to a more soluble form,  $\text{Hg}^{++}$ . Therefore, our approach was to contact elemental mercury vapor with either aqueous or gaseous oxidants, oxidized it and scrubbed it into the solution.

In summary, the objectives of this research were:

- (1) Measure and model mercury absorption into aqueous solution typical of limestone slurry scrubbing.

(2) Quantify the reaction kinetics and clarify the mechanisms of mercury reaction with oxidants in aqueous solutions.

Although primarily directed at developing technologies for mercury abatement from power plant emissions, this work also provides basic scientific data for the advantages of the entire chemical engineering community.

## Chapter 2 Literature Review

### 2.1 UNDERSTANDING MERCURY

In the periodic table of the elements, mercury is categorized in the group of elements known as the transition metals. It occupies Group IIB along with the elements Zn and Cd, yet it has some rather unusual physical and chemical properties that distinguish itself from the other transition metals. For example, mercury is the only metal that is a liquid at normal room temperature. As a result, elemental mercury has a substantial vapor pressure, even at room temperature, and it is relatively easily vaporized. This is one of the reasons that mercury is found everywhere, including ambient air, work area atmospheres and natural waters.

Mercury exists in ambient air predominantly in the gaseous form as individual mercury atoms rather than in the particulate phase, as is the case for other transition metals, e.g., Cd, Zn, Cu, Ni and Pb. The relatively high first ionization potential for mercury (241 kcal/mole), even if compared with those of the noble metals Ag (175 kcal/mole), Pd (192 kcal/mole), Pt (207 kcal/mole) and Au (213 kcal/mole), places it in the same position with the inert gas Ra (248 kcal/mole). This may explain the existence of mercury in the atmosphere primarily in the reduced form ( $\text{Hg}^0$ ), even though the atmospheric environment is well known for its oxidizing properties, as demonstrated by the formation of acid rain and the occurrence of oxidants and photochemical smog (Schroeder et al.,

1991). The unique absorbency at 253.7 nm of elemental mercury permits the use of cold vapor atomic absorption spectroscopy for mercury analysis.

Mercury is found in nature in many forms but predominantly it is present as cinnabar, HgS. In the United States, the average mined ore contains approximately 5 pounds of mercury per ton of ore.

### 2.1.1 Physical-Chemical Properties

Literature review gave most of the physical-chemical properties of mercury. They are listed in table 2.1.

Table 2.1 Physical-chemical properties of elemental mercury and mercuric chloride.

Property	25°C	55°C
$D_{\text{Hg-H}_2\text{O}}^{\text{a}}$ ( $\text{cm}^2\text{sec}^{-1}$ )	$1.19 \times 10^{-5}$	$2.21 \times 10^{-5}$
$D_{\text{Hg}^{++}\text{-H}_2\text{O}}^{\text{b}}$ ( $\text{cm}^2\text{sec}^{-1}$ )	$8.47 \times 10^{-6}$	$1.65 \times 10^{-5}$
$H_{\text{Hg}}^{\text{c}}$ ( $\text{atm M}^{-1}$ )	8.91	35.64
$D_{\text{Hg(g)-N}_2}^{\text{d}}$ ( $\text{cm}^2\text{sec}^{-1}$ ) (1 atm)	0.13	0.16
$D_{\text{Hg(g)-Air}}^{\text{e}}$ ( $\text{cm}^2\text{sec}^{-1}$ ) (1 atm)	0.15	0.18
Vapor pressure of liquid $\text{Hg}^{\text{c}}$ (atm)	$2.70 \times 10^{-6}$	$2.43 \times 10^{-5}$
Vapor pressure of solid $\text{HgCl}_2^{\text{c}}$ (atm)	$2.53 \times 10^{-7}$	$4.57 \times 10^{-6}$
Water solubility of liquid $\text{Hg}^{\text{c}}$ (M)	$3.05 \times 10^{-7}$	$6.82 \times 10^{-7}$
Water solubility of solid $\text{HgCl}_2^{\text{c}}$ (M)	0.269	0.575
Henry's constant of $\text{Hg}^{\text{c}}$ ( $\text{atm M}^{-1}$ )	8.91	35.64
Henry's constant of $\text{HgCl}_2^{\text{c}}$ ( $\text{atm M}^{-1}$ )	$9.41 \times 10^{-7}$	$7.95 \times 10^{-6}$

### **2.1.2 Transportation and Fate of Mercury Emissions**

Mercury is released into the atmosphere not only by industrial processes and other human activities, but also from many natural sources. Once discharged in the atmosphere, mercury vapor and small particulates of divalent inorganic mercury compounds can stay there for long times and travel long distances. Ultimately it is deposited on the soil or into lakes, rivers, and oceans.

Atmospheric dispersion models have been developed to predict the rate of deposition of mercury at various distance from a point source, such as a specific power plant (Vaughan et al., 1975). After deposition in lakes and streams, mercury is accumulated in the sediments where it can be converted to methylmercury by microorganisms, principally sulfate-reducing bacteria. However, the mechanism by which methylmercury becomes incorporated in the food chain in the lake is not fully understood. A model named Mercury in Temperate Lakes (MTL) is being developed by the Electric Power Research Institute (EPRI) to simulate the complex mercury interaction in lakes (Douglas, 1991). By combining atmospheric, soil and lake dispersion models, the impact of mercury emission can be estimated.

### **2.1.3 Characteristics of Mercury in Flue Gases**

Knowledge of the vapor pressure of mercury is important in determining how much mercury is discharged to the atmosphere from various processes when the conditions are such that the vapor is in equilibrium with liquid mercury in the system. Typically, the concentration of Hg is in the range of 0.0001 to 0.0006 ppm from Coal Fired Power Plant emissions and 0.01 to 0.1 ppm from Waste

Incineration emissions (Hall, 1991). Since the concentration of mercury in the flue gas does not approach the equilibrium value even as it cools when passing through various gas treatment systems, homogeneous condensation of mercury vapor does not occur. However, at lower temperatures mercury vapor may be adsorbed onto fly ash particles or other surfaces.

The form of mercury in the flue gas may determine the optimum method of separation. Generally, there are three phases in coal combustion where trace elements exist in different physical forms (Gleiser, 1993). For those elements that are not volatilized or, if volatilized, condense and coalesce later, the removal mechanism usually is filtration in the dust collector which can achieve at least 90% removal. However, in comparison to these elements, a great portion of the mercury emission often exists as gas at very low concentration, namely, 0.1-0.6 ppb, which is extremely difficult to separate.

Mercury, which is mainly present in the coal as mercury sulfide, is oxidized to  $\text{HgO}$  during combustion. The oxide is converted to the elemental form which is the thermodynamically stable species at the high temperatures of the combustion zone. Most of the mercury in the coal is vaporized and, generally, about 10% is associated with the fly ash. The remaining 90% of the total mercury is in the vapor phase at the air preheater outlet (Noblett et al., 1993). Elemental mercury and a less volatile form, mercuric chloride are the two primary forms in the vapor phase. The relatively high concentration of  $\text{HCl}$  ( $150 \text{ mg/m}^3$ ) in the flue gases makes the existence of  $\text{HgCl}_2$  possible (Meij, 1991). This explanation was also supported by other researchers (DeVito et al, 1992; Brna, 1992; Nakazato, 1990). On the other hand, some other investigators even found low

coal chlorine contents could produce a significant amount of ionic mercury (Felsvang, 1993). The relative ratios of the oxidized to the elemental form of mercury have primarily been speculative to date. A recently developed mercury speciation method has been reported and the limited results indicate 50-90% of the mercury in these measurements is oxidized (Bloom, 1991). Essentially all water soluble mercuric chloride ( $\text{HgCl}_2$ ) is removed by conventional FGD systems, while elemental mercury is unaffected (Wesnor, 1993; Noblett et al., 1993). Therefore, the overall removal efficiency of mercury will depend on the speciation of mercury inlet in the flue gas. This might also be one of the reasons that mercury removal efficiencies are widely scattered in different power plants.

#### **2.1.4 The Question of Permanent Capture and Ultimate Disposal**

Bergstrom (1986) reported that over a period of 14 days, 20-15% of the mercury in fly ash from a fabric filter evaporated at room temperature. Lindberg (1987) studied the loss of mercury vapor from solid wastes and storage ponds near chlor-alkali plants in the eastern United States. In controlled experiments he reported that the evaporation of mercury escalated dramatically as the surface temperature of the solid waste increased above 70°F. Further, at temperatures near 86°F, the measured mercury concentrations in the vicinity of a waste pond approached the EPA's 1  $\mu\text{g}/\text{m}^3$  ambient air quality standard. Similarly, a study demonstrated that evaporation of mercury from soils rich in volcanic ash was essentially parallel to the mercury vaporization function which is exponential with temperature (Siegel and Siegel, 1988). These studies suggest a substantial problem in maintaining mercury capture using a dry scrubber system. This would

be a particular concern in warm climates where dark fly ash may attain a temperature of 140°F, baking in the summer sun before being covered.

## **2.2 CONTROL TECHNOLOGIES**

### **2.2.1 Control the Mercury Content of the Fuel**

One of the direct approaches to reducing mercury emissions from combustion is to reduce the mercury content of the fuel. In the case of coal, switching to a coal with a lower average mercury concentration or to a cleaned coal in which a reduced mercury has been achieved through the cleaning process will result in lower emissions. The mercury content of coal varies widely. In a study of 101 coals the observed mercury concentration varied from 0.2 to 1.6 ppm. Literature values were found in the range from 0.01 to 8.0 ppm for subbituminous coal, and from < 0.01 to 3.3 ppm for bituminous coal (Radian Corporation, 1989). For a coal with a heating value of 13100 Btu/lb, the mercury emissions per  $10^{12}$  Btu input would range from 0.7 to 620 pounds for the extreme concentrations of 0.01 and 8.0 ppm mercury, respectively. Although the freedom to switch to a coal lower in mercury content will probably be restricted by other considerations, the option of coal switching as a means of reducing mercury emissions is one to be considered.

Coal cleaning is another means of reducing the input of mercury to the combustion system. In coal cleaning, most of the trace elements are removed to the same extent as the ash. Mercury removal, however, is lower and much more variable than many of the other trace elements (DeVito et al., 1993). As in the case of switching to low mercury coal, other considerations may take precedence

over the use of a cleaned coal for the specific purpose of lowering mercury input, but again, it is an option that may prove useful.

### **2.2.2 Particulate Control Devices**

Devices to control particulate emissions are now standard on coal combustion facilities. The degree to which such devices reduce mercury emissions depends on the conditions upstream of and within the device. Mercury is assumed to be entirely in the elemental vapor state when it leaves the combustion chamber. Mercury vapor will pass through the collection device unaffected because the concentration in the flue gas is far below the equilibrium value. However, if the flue gas has been sufficiently cooled, some of the mercury vapor may be sorbed onto fly ash particles or other surfaces. In this case, the electrostatic precipitator (ESP), baghouse, or other collection device would remove some or all of the particles carrying mercury.

#### **2.2.2.1 *Electrostatic Precipitator (ESP)***

Radian (1989) reported that, in the literature prior to 1965, an average of 50% mercury removal was reported by the data on ESPs. However, the report pointed out that much of the data was suspect because of the failure to close mass balances due to analytical difficulties. Huang et al.. (1991) summarized mercury removal efficiencies in the literature and showed a mercury collection efficiency of 25-50% for cold and 0% for hot electrostatic precipitators. The authors also added that there were deficits in the mass balance for mercury in some of the results so that these values can only be considered tentative.

#### **2.2.2.2      *Fabric Filter***

Fabric filters effectively remove particles from flue gas so that mercury removal depends on the association of mercury with particles in the same manner as that for ESP, which is discussed in section 2.2.2.1. Data for fabric filters is equally sparse and inconclusive. A range of 50-90% mercury removal was indicated in a limited numbers of fabric filter systems (Smith, 1987; Chow, 1991).

#### **2.2.3    *Wet Scrubbing***

Flue Gas Desulfurization (FGD) systems, using limestone slurry scrubbing for removing sulfur dioxide, cool the flue gas and, as a result, some mercury may be adsorbed onto fly ash particles and be removed from the flue gas in the particulate collection device. Mercury removal efficiency in wet FGD process has the same wide ranges of values as seen with particulate collection devices. The literature reported 20-90% mercury removal based on very few available results (Radian Corporation, 1989; Huang et al., 1991).

Multistage condensing wet scrubbers and electrostatic precipitators followed by wet scrubbers (ESP/WS) are proven technology in Europe. Their use was originally directed to the economical removal of acid gases. However, Reimann (1986) reported 80-90% mercury removal with an ESP/WS configuration and the use of the organo-sulfur precipitant, to capture and stabilize the mercury in the scrubber blow down. More recently, greater than 90% mercury removal was reported by employing a two stage condensing wet scrubber. Since elemental mercury vapor did not completely condense at the 100-140°F operating temperatures of wet scrubber, the outlet emissions were entirely elemental

mercury. Some vendors thus believe that scrubbers work better when the dominant species is the highly soluble mercuric chloride. However, some removal of elemental mercury can be expected by the mechanism of fine particle impacting, diffusion, and possibly by dissolution in acidic zones (Volland, 1991).

Other investigators reviewed the operating conditions for mercury removal in wet flue gas desulfurization systems. Their results are listed in table 2.2.

Table 2.2 Parameters affecting removal of vapor-phase mercury in wet absorber (Noblett et al., 1993).

Parameter	Comments
L/G	Increased gas/liquid surface area increases removal.
Absorber Internals	Trays or packing can increase gas/liquid surface area and improve removal. Position of headers and nozzles can affect spray coverage and spray interaction, affecting surface area.
Tower Height	Increased tower height or tower width will increase contact time and may improve removal.
Slurry Chemistry (including pH)	If there is significant liquid-film resistance, slurry chemistry could affect the form of absorbed substance and/or solubility of compounds containing the substance.
Additives or Neutralizing Agents	If removal is influenced by liquid-film resistance, then complexing, precipitating, or increasing solubility of the absorbed substance could improve removal.
Gas Velocity	Gas velocity will affect gas/liquid contact time.
Oxidation Mode	Oxidation mode may affect form and solubility of absorbed substances, affecting removal in situations where liquid resistance is important.

Vogg et al. (1986) studied mercury removal by wet scrubbing methods in laboratory scale experiments. They showed that mercuric chloride could be conveniently and very effectively eliminated from the gas phase through condensation. They also observed the possibility of mercury loss if divalent mercury was reduced, e.g. by sulfur dioxide. They then suggested that this could be counteracted by higher chloride concentrations, by a strongly acid scrubbing

solution, or if possible, by lowering the temperatures or adding oxidants, such as ferric chloride.

#### **2.2.4 Spray-Dryer Scrubbing**

Spray dryer absorption is an alternative technology for desulfurization of flue gases. A wide range of 20-95% mercury removal was reported based on a few sets of data (Gleiser, 1993).

#### **2.2.5 Modified Mercury Control Processes**

The first option of modifying a FGD system is the use of carbon. Felsvang et al. conducted spray dryer absorption tests in three pilot plants used for control of mercury emissions from coal-fired power plants. By injecting activated carbon, improvements of mercury removal were achieved (Felsvang, 1993). Similar modified FGD technology increased the mercury removal efficiency to 60-90% (Gleiser, 1993; Guest, 1991). Commercial processes for injection of activated carbon in spray dryer systems for incinerators have been available (Niro, 1987), but the applicability to coal-fired power plants still is a problem.

Another option is to use additives specifically designed for mercury removal. Japanese investigators have applied a liquid chelating agent injection system and a sodium hypochlorite injection system to a limestone slurry scrubber and have achieved 90% mercury removal (Nakazato, 1990). The addition of a chlorine containing material such as sodium chloride improved overall mercury removal by changing the speciation of inlet mercury, based on testing pilot scale coal-fired power plants (Felsvang, 1993).

Other additives, such as sodium sulfide and sodium hydrosulfide for spray dryer systems and polysulfide for wet scrubbing systems have also been reported (Zohourlsen, 1991; Guest, 1991). Since the highly stable and non-volatile mercuric sulfide species is formed, this process theoretically should achieve near permanent capture of the mercury. However, the use of sodium sulfide prompts certain safety concerns with handling as well as concern for corrosion problems. Some experimental work using these additive systems on incinerator flue gas were conducted with promising results, but no work has been reported in which the systems have been applied to coal combustion flue gas.

A German company has commercialized a simplified sulfur dioxide and mercury scrubbing process called MercOx (Parkinson, 1996). In their process, a 35% aqueous solution of hydrogen peroxide is sprayed into the flue gas. Elemental mercury is oxidized by hydrogen peroxide to Hg(II) and remains in the solution. In a parallel reaction, a water spray converts SO<sub>2</sub> to sulfuric acid. As a result, all gaseous pollutants are converted and trapped in the solution. Dissolved mercury is removed by ion exchange and the acids are neutralized to salts and precipitated gypsum. In recent pilot test treating a 500 m<sup>3</sup>/hr flue gas stream at a sludge incinerator, mercury concentrations were reduced from a few hundred µg/m<sup>3</sup> to 20 µg/m<sup>3</sup>, well below the 50 µg/m<sup>3</sup> German limit. The capital cost for a 18000 m<sup>3</sup>/hr unit is only about one quarter that of a conventional system while the operating cost is 20-25% less.

## **2.3 MERCURY EMISSION STANDARDS**

Following the emphasis on the regulation of sulfur oxides, nitrogen oxides, and particulate matter in the 1970s and 1980s, attention broadened to include concern over air toxics in the mid 1980s and this has continued (Schroeder et al., 1987). The Clean Air Amendments (CAAA) of 1990 addressed the subject of air toxics under section 112. This section calls for the promulgation of emission standards for pollutants not previously regulated under the National Ambient Air Quality Standards. A list of 189 elements and chemicals is specified in the law as subject to control. For mercury emission, because of the wide variability of mercury levels in coal, difficulties in sampling and analysis, and variations in the way in which mercury is partitioned in the various combustors in use, the information on utility emissions was insufficient for promulgation of regulation. Thus, the law mandates three studies related to health effects, control technologies and costs of control to develop the required information.

### **2.3.1 Coal-Fired Power Plants**

Since the CAAA prohibits EPA from setting standards on mercury emissions from utility power plants until all of the studies have been completed, it will undoubtedly take considerable time for the results of the studies to be reviewed and decisions made as to whether any standards will be set for mercury. It would seem that late 1996 or early 1997 might be the earliest that anything definite regarding new standards will be decided.

### **2.3.2 Municipal Waste Combustors**

As a result of extensive research on mercury's impact on the ecosystem, Sweden has set a mercury emissions limit for Municipal Solid Waste incinerators equivalent to about 40  $\mu\text{g/dscm}$  corrected to 7% oxygen. The Dutch limit is equivalent to about 70  $\mu\text{g/dscm}$ . The new German limit for the sum of cadmium and mercury emissions is 140  $\mu\text{g/dscm}$  corrected to 7% oxygen (Volland, 1991). Most recently, U. S. EPA has set the limit for large and small Municipal Waste Combustion plants to be 80  $\mu\text{g/dscm}$  (35 gr/million dscf) or 85% reduction in mercury emissions (Federal Register, 1995). This mercury emission standard went into effect on June 19, 1996 for new sources and December 19, 1995 for existing sources.

## **2.4 THEORY OF SIMULTANEOUS MASS TRANSFER WITH CHEMICAL REACTION**

### **2.4.1 Film Theory**

Several models have been developed to describe mass transfer at a fluid phase boundary. The earliest and simplest is the film theory proposed by Whitman (1923). This model is based on the assumption that for a fluid flowing turbulently over a solid, the entire resistance to mass transfer resides in a stagnant film in the fluid next to the surface. It pictures a stagnant film of thickness at the surface of the liquid next to the gas. While the rest of the liquid is kept uniform in composition by agitation, the concentration in the film falls from  $\frac{P_i}{H}$  at its surface to  $C^*$  at its inner edge, where  $C^*$  is the average concentration of dissolved gas in the bulk liquid. There is no convection in the film, and dissolved gas crosses it by

molecular diffusion alone. The mass transfer coefficient is equal to  $\frac{D}{\delta}$ , where  $\delta$  is the thickness of the stagnant film.

#### **2.4.2 Penetration Theory**

Higbie (1935) suggested a penetration theory for transfer across a gas-liquid interface. This theory assumes that the liquid surface consists of small fluid elements that contact the gas phase for an average time, after which they penetrate into the bulk liquid. Each element is then replaced by another element from the bulk liquid phase. The penetration theory predicts the mass transfer coefficient to be  $2\sqrt{\frac{D}{\pi t_s}}$ , where  $t_s$  is the exposure time of the fluid element.

#### **2.4.3 Surface Renewal Theory**

On the basis of the penetration theory, Danckwerts (1970) suggested that the constant exposure time in penetration theory be replaced by an average exposure time determined from an assumed time distribution. The chance of an element being replaced on the surface was independent of the time during which it had been exposed. For this model the mass transfer coefficient is equal to  $\sqrt{Ds}$ , where  $s$  is the rate of surface renewal and is equal to the reciprocal of the exposure time of the elements.

#### **2.4.4 The Effects of Chemical Reactions**

The above discussed three models may be used to predict the effect of a chemical reaction on the rate of absorption. Predictions based on the three models are closely similar, except in regard to the effect of the diffusivity of the solute gas and of dissolved reactants on the rate of absorption. For instance, the film model

predicts that mass transfer coefficient is proportional to diffusivity while both penetration and surface renewal theory predict that it varies as  $\sqrt{D}$ . It is difficult to make an accurate test of this dependence, since the diffusivities of typical solute gases do not cover a wide range and are difficult to determine accurately. For the same reasons, the dependence of mass transfer coefficient on the diffusivity is usually of relatively lesser importance. In most cases the film theory would lead to almost the same predictions as the penetration and surface renewal theory. Furthermore, the difference between predictions made on the basis of the three models discussed above will be less than the uncertainties about the values of the physical quantities used in the calculation. The three models can thus be regarded as interchangeable for many purposes, and it is then merely a question of convenience which of the three is used.

The governing equation, in the case of an irreversible first-order reaction, is given by the material balance:

$$D \frac{\partial^2 C}{\partial x^2} = \frac{\partial C}{\partial t} + k_1 C \quad (2-1)$$

with the following boundary conditions:

$$1. C = 0 \quad \text{at } x > 0 \text{ and } t = 0 \quad (2-2)$$

$$2. C = \frac{P_i}{H} \quad \text{at } x = 0 \text{ and } t > 0 \quad (2-3)$$

$$3. C = 0 \quad \text{at } x = \infty \text{ and } t > 0 \quad (2-4)$$

The solution using the surface renewal model is detailed in Danckwerts (1970), where  $\bar{C}$  is the average concentration over time:

$$\bar{C} = \frac{P_i}{H} \exp\left(-\frac{x k_1^\circ}{D} \sqrt{1 + \frac{D k_1}{k_1^{\circ 2}}}\right) \quad (2-5)$$

The average rate of absorption per unit area of gas-liquid interface, or flux, is obtained from:

$$N = -D \left( \frac{d\bar{C}}{dx} \right)_{x=0} = k_l' \left( \frac{P_i}{H} \right) \sqrt{1 + \frac{D k_1}{k_l'^2}} \quad (2-6)$$

Similarly, for second-order irreversible reaction, this theory predicts the average flux to be:

$$N = k_l' \left( \frac{P_i}{H} \right) \sqrt{1 + \frac{2 D k_2 P_i}{3 k_l'^2}} \quad (2-7)$$

If the reaction is fast enough (large  $k_1$  and  $k_2$ ), the simplified fluxes are:

$$N = \left( \frac{P_i}{H} \right) \sqrt{D k_1} \quad (2-8)$$

$$\text{and } N = \left( \frac{P_i}{H} \right) \sqrt{\frac{2 D k_2 P_i}{3}} \quad (2-9)$$

In the above derivation,  $N$  is flux,  $k_1$  and  $k_2$  are first-order and second-order rate constants,  $D$  is the diffusion coefficient in liquid phase,  $k_l'$  is liquid film physical mass transfer coefficient,  $H$  is Henry's constant,  $P_i$  is interfacial partial pressure of the dissolving gas,  $C$  is the concentration of the gas in the liquid,  $x$  is the distance below the gas-liquid surface and  $t$  is time.

In the above expressions, the quantity  $\sqrt{1 + \frac{D k_1}{k_l'^2}}$  is known as the enhancement factor  $E$ .  $E$  is a measure of the amount of dissolved gas which reacts in the diffusion film near the surface, compared to that which reaches the bulk liquid in the unreacted state. If  $E$  is 1, it represents a physical absorption with no reaction, in which case the dissolved gas diffuses from the surface to the bulk without reaction on the way. If  $E \gg 1$ , the dissolved gas all reacts in the film and none diffuses in the unreacted state into the bulk of the liquid. Thus the film

thickness, or the value of  $k_1$ , is irrelevant and does not appear in the expression for flux  $N$ .

## 2.5 AQUEOUS PHASE REACTIONS

### 2.5.1 Reduction of $\text{Hg}^{++}$ by Sulfite

There are several aqueous phase reactions that involve mercury species. The most important one is reduction of  $\text{Hg}^{2+}$  by sulfite. Munthe et al. (1991) proposed that  $\text{Hg}^{2+}$  could be reduced by aqueous sulfite solutions with the formation of an unstable intermediate,  $\text{HgSO}_3$ , followed by decomposition to  $\text{Hg}^+$  which in turn is rapidly reduced to  $\text{Hg}^\circ$ . Using the empirical equation derived by Dyrssen and Wedborg (1991), they calculated that  $\log K_1 = 12.7$  and  $\log K_2 = 11.4$  where  $K_1$  and  $K_2$  are equilibrium constants of the following two equations, respectively:

On the other hand, the reaction:

should be considered according to the observed dependence of apparent rate constants on the concentration of excess  $\text{HSO}_3^-$ . The  $\text{Hg}^+$  ion formed would then be rapidly reduced to elemental Hg by the following two reactions:

When a low concentration of  $\text{SO}_2(\text{g})$  ( $5\text{g/m}^3$ ,  $25^\circ\text{C}$ ) was present, the rate of conversion of  $\text{Hg}(\text{SO}_3)_2^{2-}$  to  $\text{Hg}^\circ$  was significant at  $\text{pH} < 5.5$ . At higher concentrations of  $\text{SO}_2(\text{g})$ , significant reduction occurs at slightly lower pH.

### 2.5.2 Reaction between $\text{HgCl}_2$ and $\text{S}_2\text{O}_3^{2-}$

The reaction between  $\text{HgCl}_2$  and  $\text{S}_2\text{O}_3^{2-}$  is also reported in literature (Barbieri et al., 1960):

### 2.5.3 Oxidation of $\text{Hg}^\circ$ and $\text{Hg}^{++}$ by $\text{KMnO}_4\text{-H}_2\text{SO}_4$

It is well known that acidic  $\text{KMnO}_4$  solution reacts with  $\text{Hg}^\circ$  (Monkman et al., 1956). Recent work performed at Radian indicates that  $\text{KMnO}_4$  also reacts with  $\text{Hg}^{++}$  even though the products are not known yet (personal communication with Dr. Carl Richardson, 1994). Hara (1975) studied the reaction of  $\text{Hg}^\circ$ -air with  $\text{KMnO}_4\text{-H}_2\text{SO}_4$  in a impinger system. The author concluded that dissolved  $\text{KMnO}_4$  changed to  $\text{MnO}_2$ , and granules of  $\text{MnO}_2$  precipitated out gradually. The greater part of captured mercury was adsorbed on precipitated  $\text{MnO}_2$ , and the amount of mercury captured in liquid phase was very little. He further indicated that  $\text{KMnO}_4$  played a great part in the capture of mercury, and  $\text{H}_2\text{SO}_4$  was necessary for the adsorption of mercury on  $\text{MnO}_2$ .

Although  $\text{KMnO}_4\text{-H}_2\text{SO}_4$  has been used in mercury analytical procedures and in mercury flue gas field sampling, no kinetic information has been reported so far. The most probable stoichiometry is shown below:

#### 2.5.4 Oxidation of Hg<sup>0</sup> and Reduction of Hg<sup>2+</sup> by H<sub>2</sub>O<sub>2</sub>

Aqueous H<sub>2</sub>O<sub>2</sub> can either act as a source of oxidizing agent for Hg<sup>0</sup> or a reducing agent for Hg<sup>2+</sup> (Brosset, 1987):

The oxidation predominates when pH is below 5.5 and the reduction predominates when pH is above 5.5.

#### 2.5.5 Oxidation of Hg<sup>0</sup> by Chlorine, Hypochlorous Acid and Hypochlorite

Menke and Wallis (1980) studied the rate of Hg<sup>0</sup> removal by Cl<sub>2</sub> at different levels of relative humidity. Excess chlorine was present so the pseudo first order rate constant could be obtained. However, due to the complexity of the reaction, an upper limit of the rate constant was reported instead. The authors pointed out that their results may indicate the formation of products other than HgCl<sub>2</sub>.

The kinetics of absorption of mercury in aqueous hypochlorous acid and hypochlorite were studied in a disc column at 30°C by Nene and Rane (1981). Table 2.3 gives the concentration ranges of the reactants used in their study.

Table 2.3 Concentration ranges of reactants used in Nene and Rane's study (1981).

Compound	Concentration Range (M)
HOCl	2.6 - 9.5x10 <sup>-3</sup>
NaOCl	6.7x10 <sup>-3</sup> - 0.03
KOCl	5.5x10 <sup>-3</sup>
NaCl	4.4
KCl	0.34

The authors found that hypochlorous acid was much more reactive than hypochlorite. In the case of hypochlorite, reactivity was further increased in the presence of sodium chloride. They also compared the reactivity of sodium and potassium hypochlorites and found the latter was more reactive with mercury. They found that the reaction between mercury and hypochlorite was first order with respect to each of them.

Kobayashi (1987) investigated the oxidation of elemental mercury by bubbling  $\text{Hg}^0$  vapor into  $\text{NaOCl}$ . The concentration of dissolved mercury increased as  $\text{OCl}^-$  concentration was increased from 0.0014 to 0.014 mM. The initial rate of mercury oxidation was reported to be independent of the  $\text{OCl}^-$  concentration, suggesting that the oxidation rate was not the rate-determining step under the experimental conditions. The author concluded that the reaction was zero order in  $\text{OCl}^-$ . He then proposed the following possible reactions to account for the observed 1:2 stoichiometry:

This mechanism was consistent with the observation that the concentration of dissolved mercury increased from 0.33 to 0.57 mg/l when pH was decreased from 8.1 to 1.2.

#### **2.5.6 Oxidation of $\text{Hg}^0$ by Ozone**

The oxidation of elemental mercury by aqueous ozone was studied by Iverfeldt and Lindqvist (1986) and more recently by Munthe (1992). The former

reported that the absorption of mercury in the water phase was increased by three orders of magnitude with O<sub>3</sub> present. The latter reported a second order rate constant of  $(4.7 \pm 2.2) \times 10^7 \text{ M}^{-1}\text{s}^{-1}$ .

### 2.5.7 Oxidation of Hg<sup>0</sup> by Organoperoxy Compounds

Wigfield and Perkins (1985) studied the aqueous oxidation of Hg<sup>0</sup> by a series of peroxy compounds including peracetic acid, m-chloroperoxybenzoic acid, ethylhydroperoxide and tert-butyl hydroperoxide. The authors found that peracetic acid and m-chloroperoxybenzoic acid oxidized Hg<sup>0</sup> to Hg<sup>+</sup> and Hg<sup>++</sup>, suggesting that the presence of a carbonyl group enhances the reactivity of peroxides. Control experiments with acetic and benzoic acid did not result in Hg<sup>0</sup> oxidation.

## 2.6 GAS PHASE REACTIONS

The reactions of elemental mercury vapor with flue gas components were investigated by using a 17 kW propane fired flue gas generator and a continuous flow reactor (Hall et al., 1991). It was concluded that elemental mercury was readily oxidized by Cl<sub>2</sub> and HCl both at room and at elevated temperatures up to 900°C. Mercury also reacted with oxygen if a catalyst, such as activated carbon, was present. A slow reaction between elemental mercury and NO<sub>2</sub> was also observed at 340°C. On the other hand, NH<sub>3</sub>, N<sub>2</sub>O, SO<sub>2</sub> or H<sub>2</sub>S did not react with elemental mercury under similar conditions. They proposed the following possible reactions:

## 2.7 EXISTING PROBLEMS

One of the primary reasons that additional studies of mercury emissions are required is that much uncertainty exists regarding the performance of various control technologies with respect to reducing mercury emissions. There is so much scatter in the results reported that definitive performance measures cannot be established with any confidence. This variability in the data was due, in part, to the fact that the mercury concentrations encountered are extremely low so that difficulties with sampling and analysis can produce unreliable data. Another problem is that there is a lack of fundamental understanding of the mechanisms involved when mercury is removed from flue gas. It is clear that temperature is a factor because both electrostatic precipitators and wet sulfur dioxide scrubbers remove mercury more effectively at low temperature than at high temperature. This is not the result of homogeneous condensation of mercury vapor at equilibrium because the concentration of mercury in flue gas is in the mg/m<sup>3</sup> range, while the equilibrium concentration of mercury vapor is orders of magnitude higher. Many reports in the literature indicate that mercury retained in the system is found associated with the fly ash. Thus the nature of the fly ash

becomes an important factor. Variations in the fly ash between tests may play a roll in the observed different results.

Additional technologies used to modify the existing FGD systems have achieved some successes in mercury emission control (Niro, 1987), but achievable removals for these processes when applied to the more dilute mercury concentrations found in flue gases from coal-fired power plants are not yet known.

### Chapter 3 Experimental Apparatus and Analytical Methods

The rate of mercury absorption was measured in the stirred cell reactor system shown in figure 3.1. Two identical reactors, one stainless steel and the other coated with Teflon, were tested for mercury absorption/desorption. As will be discussed in detail in chapter 5, results from permanganate experiments conducted in the old reactor necessitated the construction of the second Teflon coated stirred tank reactor.

Figure 3.1 The stirred tank reactor systems for mercury absorption. Mercury permeation tube is inside the U-tube immersed in water bath. TC is temperature controller, FM is mass flow meter.

### 3.1 TEFLON COATED STIRRED TANK REACTOR

The purpose of the stirred tank reactor experiments was to simulate absorption of mercury across the gas-liquid interface of a droplet, a bubble or packing in a commercial absorber. The solution composition was varied in order to find the most efficient absorbent for mercury abatement under typical limestone slurry scrubbing conditions or for add-on commercial application to existing wet scrubber systems. The stirred tank reactor system was designed to provide a bulk gas phase with a known mercury concentration in contact with liquid solution. The area of gas-liquid contact at the interface is known by maintaining a flat, undisturbed surface.

Figure 3.2 gives the dimensions of the glass reactor. The cylindrical reactor had a 10 cm diameter and 16 cm height. The total volume of the reactor was 1.295 liters. The volume of solution used in each experiment was 1.06 liters. The gas-liquid contact area was 81 cm<sup>2</sup>. The reactor vessel was a thick glass cylinder with Teflon coated 316 stainless steel plates sealed to the top and bottom by thick gasket clamps. Four  $\frac{3}{8}$  inch wide, equally-spaced, Teflon-coated, 316 stainless steel baffles were welded to the bottom plate. The length of the baffles was long enough to extend to the main body of the gas phase. The bottom plate contained ports for liquid inlet and outlet. The top plate contained ports for the gas inlet and outlet, solution injection, Teflon coated thermocouple (Omega K type), Epoxy Body Gel-Filled pH probe (Accumet SN 5115079) and a glass U-tube pressure gage partially filled with water. Viton lip seals (JM Clipper Oil Seals) were used for both gas and liquid phase. The advantage of the Viton seal

was that it resisted acid or strong oxidizer corrosion. It also provided a reliable seal against leak compare to earlier spring seals. The Viton seals must be replaced regularly, depending on the frequency of the agitation and the degree of corrosion of the liquid.

Figure 3.2 Dimensions of the gas-liquid contactor.

---

The gas inlet was at the near center of the top plate, directly above the gas agitator blade, to ensure that the inlet gas was properly mixed. The proper mix of gas was also ensured by four baffles extended from the liquid phase to the gas phase. The reactor was equipped with Teflon-coated gas phase and liquid phase agitators which were independently controlled. The dimensions of the agitators are given in figure 3.3. The gas agitator was a six-blade flat turbine with a diameter of 6.35 cm. The liquid phase was agitated by a three-blade marine type

agitator with a diameter of 5.08 cm. FisherBrand StedFast Stirrers (Model SL 1200) were used to drive gas and liquid phase agitators. Both agitator speeds were measured by a hand-held Ono Sokki HT-4100 digital tachometer, and for most of the experiments the agitation speed for both gas and liquid phases was between 500 and 700 rpm.

Figure 3.3 Agitator design and dimension.

---

Quarter inch Teflon tubing, fittings and valves were used for all connections before the mercury analyzer. Larger diameter flexible tubing, such as 1 inch Tygon tubing was used in the vent line to keep the reactor pressure low (near 1 atm). An empty 100 ml glass Erlenmeyer flask was connected after the reactor outlet and before the analyzer to capture any water vapor or liquid.

The mercury permeation tube was immersed in a water bath with temperature maintained by Lauda Immersion Circulator B. The experiments were

performed at both 25 and 55°C. The solution temperature was measured by an Omega K type Teflon coated thermal couple inserted into the reactor. An Omegalux FGH101-060 heating tape wrapped around the glass cylinder of the reactor was controlled by an Omega temperature controller which was connected to the thermal couple. Solution pH was continuously measured by an Accumet SN 5115079 Pencil-Thin Epoxy Body Gel-Filled pH probe inserted into the reactor and a Corning pH meter 125.

### **3.2 ELEMENTAL MERCURY SOURCE**

Synthetic flue gas was prepared by mixing a known amount of elemental mercury vapor with nitrogen or air to produce a constant flow rate of mercury vapor to the reactor. Elemental mercury vapor was obtained from a commercially available mercury permeation tube (VICI Metronics) which emits steady trace amounts of mercury into a known dilution flow rate. By maintaining a reservoir of the liquid mercury at a constant temperature in the water bath, the mercury vapor pressure remains constant and provides the constant driving force for diffusion through the membrane wall. Actual rates of mercury diffusion can be obtained from manufacturer for a particular permeation tube. Two types of mercury permeation tubes were used in this study to provide different inlet mercury concentrations. The manufacturer calibrated permeation rate was used to determine the absolute amount of mercury in the gas stream.

The safety procedures in handling mercury can be found in appendix A. Specifications of the two mercury permeation tubes are listed in table 3.1.

Table 3.1 Specifications of the two permeation tubes used in the study.

	Tube 1	Tube 2
Type	H. E.	H. E. SR
Batch or I.D. Number	497-58697	497-65339
Tube Length (cm)	2	4
Part Number	137-030-0030-SR	137-040-0030-S56
Operating Temperature (°C)	70	90
Permeation Rate (ng/min)	167	811

The absolute mercury concentration was calculated by the following equation:

$$C = \frac{K_m P}{F} \quad (3-1)$$

where:

$$C = \text{mercury concentration (ppm by volume)} \quad (3-2)$$

$$P = \text{permeation rate (ng/min)} \quad (3-3)$$

$$F = \text{carrying gas flow rate (cc/min)} \quad (3-4)$$

$$K_m = 0.122, \text{ the molar constant} \quad (3-5)$$

The flow rate of all gas streams was maintained by Brooks mass flow controllers. The flow rate of the carrier gas (nitrogen) was kept less than 100 cc/min to ensure sufficient heat exchange between the permeation tube and water bath. The mixture of mercury and nitrogen entered the reactor through the gas inlet on the top of the plate, and mercury vapor was absorbed across an unbroken interface into a well-mixed solution. Nitrogen was added to dilute the gas before and after the reactor by a factor of ten, respectively. Nitrogen dilution into the reactor brought the total gas flow rate to 1 liter per minute. This ensures a fast absorption/desorption and adsorption/desorption equilibrium, which gave good, reproducible results. As will be discussed in more detail in chapter 8, lower gas

flow rate (200 cc/min) resulted in non-reproducible results. Nitrogen dilution after the reactor minimized the effect of water vapor on Hg analysis by cold vapor atomic absorption spectrophotometer.

### **3.3 GAS PHASE MERCURY ANALYSIS**

Typically, the concentration of mercury is in the range of 0.0001 to 0.0006 ppm from Coal Fired Power Plant emissions and 0.01 to 0.1 ppm from Waste Incineration emissions (Hall, 1991). Since our mercury analyzer can only measure total elemental mercury concentration at the lowest level of 0.001 ppm, 0.01 to 0.1 ppm mercury was used in the gas inlet.

A Cold Vapor Atomic Absorption Spectrophotometer (LDC Analytical, model 3200) was used for gas phase elemental mercury analysis. At the unique absorbency at 253.7 nm of elemental mercury, this method can measure mercury concentration at a level as low as 0.001 ppm. However, due to the limitations of the voltage readout device, the lowest detectable concentration was 0.005 ppm in our analyzer. Gas after the reactor was continuously analyzed for mercury and recorded by the strip chart recorder (Soltec Model 1242). Based on experimental results discussed in chapter 4, the analyzer configuration and gas phase mercury analysis techniques used were as follows:

- (1) 10 mV full scale output port
- (2) 10 to 15 times nitrogen dilution of the reactor outlet gas
- (3) constant 150-200 cc/min flow into analyzer and monitored by rotameter after the analyzer
- (4) 125 ml glass flask before the analyzer to catch condensed water

- (5) calibration conducted both before and after the experiment. The calibration equation based on the above two calibrations assuming linear analyzer drifting was used

### **3.4 LIQUID PHASE MERCURY ANALYSIS**

It is desirable to know the concentration of mercury in all chemical forms in the liquid phase, which also provides a mean for examining the accuracy of the gas phase material balance. Whenever feasible, liquid samples were withdrawn from the reactor at different stages of the absorption. Those samples are dumped into impingers, reduced by  $\text{SnCl}_2\text{-H}_2\text{SO}_4$  or  $\text{NaBH}_4$  solution, collected on the gold column and flushed out to elemental mercury analyzer (Hatch et al., 1968). All liquid mercury analyses were conducted at Radian International, LLC in Austin, TX.

### **3.5 TYPICAL GAS FLOW PATH AND EXPERIMENTAL OPERATION**

In a typical experiment, the mercury analyzer was turned on at least two hours before the experiment. Carrier gas nitrogen was passed through the mercury permeation tube. The permeation tube was inside a glass U-tube and the U-tube was immersed in a water bath. An inverted 2000 ml volumetric flask was filled with distilled water to automatically replenish any evaporated water from the constant temperature bath. This ensured a constant water bath depth and thus constant heating area for the U-tube. Experiments with lower water bath depth tended to give lower mercury concentration. When the water in the constant temperature bath was refilled to the top, an increased mercury concentration was

recorded. Distilled water was used in the constant temperature bath to protect and extend the life of the instrument.

The gas with elemental mercury vapor was mixed downstream with pure nitrogen to bring total flow rate to 1 l/min. This gas stream was then fed into the reactor over the solution. The reactor outlet gas was diluted ten to fifteen times with nitrogen. The permanganate scrubbing solution was prepared from equal volume of 0.1 M potassium permanganate and 10 % sulfuric acid. The majority of the gas went through the permanganate scrubber before being vented to the hood. Only a small portion (150-200 cc/min) of the gas was passed through the mercury analyzer. The gas flow rate through the analyzer was continuously monitored by a rotameter after the analyzer to ensure a constant flow rate through the analyzer in the same experiment. Rotameter off-gas was passed through the permanganate scrubber before being vented to the hood.

### **3.6 MINOR DIFFERENCES IN EXPERIMENTAL CONDITIONS AND OPERATIONS**

The experimental conditions described in section 3.5 were the optimized conditions derived from numerous try-and-error attempts. In the early stage of this research, slightly different experimental conditions were used. The total gas flow rate into the reactor was in the range of 100 to 200 cc/min. The flow rate of the diluting nitrogen was 1 to 2 l/min, significantly lower than that used later. A glass coil condenser immersed in ice bath was once used after the reactor to collect water. Experiments showed that the condensed water was actually trapped inside the condenser and was very difficult to get it out. As a result, reactor outlet mercury was still in contact with water inside the condenser. Finally, a 125 ml

glass Erlenmeyer flask was used to trap any condensed water. It was first used immersed in ice bath. Later the ice bath was eliminated. When running experiments at 25°C, there was no visible water collected in the trap. However, the water trap flask was an essential device when conducting experiments at 55°C. Visible water drops were collected in the flask. Without the water knock-out flask, those water drops would very likely plug the small tubes inside the mercury analyzer and stop the flow into the analyzer completely.

### 3.7 LIST OF INSTRUMENTS USED IN THE RESEARCH

Table 3.2 gives the instruments and their model or specifications used in this research.

Table 3.2 List of instruments used in the research.

Instrument	Model
Brooks Mass Flow Meter	9203HCO 37102, 9203HCO 37104 9205HCO 37101, 9310HCO 38404/2 9310HCO 38406/2, 8707HCO 33415
Brooks Mass Flow Controller	5878
Soltec Strip Chart Recorder	1242
Corning pH Meter	125
Lauda Constant Temperature Bath	Immersion Circulator B
Omegalux Heating Tape	FGH 101-060
Pencil-Thin Epoxy Body Gel-Filled pH probe	Accumet SN 5115079
JM Clipper Oil Seals (Viton lip seals)	0037-06362
FisherBrand StedFast Stirrers	SL 1200
Omega Temperature Controller	Rebuilt for K type Thermocouple
Soar Digital Multimeter	5030
Proportional Electric Temperature Controller	Versa-Therm 2156-4
Corning Hot Plate Stirrer	PC-351
Elemental Mercury Detector	mercuryMonitor™ 3200

## **Chapter 4 Calibration of the Apparatus**

### **4.1 MERCURY ANALYZER CALIBRATION**

A MercuryMonitor™ 3200 Elemental Mercury Detector from LDC Analytical was used for all gas phase mercury analysis. This analyzer is specially designed for application requiring the measurement of 253.7 nm ultraviolet light. The method used to determine the amount and/or concentration of elemental mercury present uses a photometric detector which measures the luminous intensity of monochromatic light that has passed through the sample and compares it with the luminous intensity of an equal light beam of fixed value such as a reference beam. Through the electronics of the instrument the result of the measurement is displayed as absorbance units.

#### **4.1.1 Analyzer Output Choice**

There are two different voltage outputs in the mercury analyzer, one is 1 volt per absorbance unit output and the other 10 mV full scale output. Both output ranges were tested for mercury detection sensitivity. Figures 4.1 and 4.2 give the results with an external digital voltmeter (Soar Model 5030). For approximately the same mercury concentration, using the 10 mV full scale output port gave a much bigger voltage response than that of 1 V per absorbance unit output port. This indicates that 10 mV full scale output port is more sensitive and flexible when large mercury concentration change occurs in one experiment when continuous mercury monitoring is necessary. We only used the 10 mV full scale output port for all our subsequent experiments.

Figure 4.1 Calibration of mercury analyzer using 1 volt per absorbance unit output port. Analyzer absorbance units sensitivity was set at R. The gas flow rate was 200 cc/min.

---

---

#### 4.1.2 Analyzer Drift and Linearity

The calibrated mercury concentration ranged from 0.005 ppm to 0.1 ppm. These calibration experiments were performed on different days with different combinations of gas synthesis systems. Not all the data points fell on the same line exactly, even when all other conditions were kept the same. This is probably due to the analyzer drift. Analyzer drift was further confirmed by calibrations conducted before and after the experiments when different readings were obtained

in later runs. From figures 4.1 and 4.2, it is obvious that linearity has been achieved over the possible range of the available permeation tubes. A minimum concentration of 0.005 ppm mercury was achieved. Lower mercury concentration could be measured as long as sufficient time was allowed for steady state to be reached and mercury loss (such as adsorption on tube wall) to be eliminated.

Figure 4.2 Calibration of mercury analyzer using 10 mV full scale output port. Analyzer absorbance units sensitivity was set at R. The gas flow rate was 200 cc/min. No drying tube was used when NO<sub>2</sub> was added to the gas phase.

---

#### 4.1.3 Interferences for Mercury Analysis

Possible interferences for mercury detection were investigated. Since water vapor could easily condense inside the system tubes or on the cell wall inside the analyzer, a 125 ml water knock out flask was installed before the analyzer. This flask is especially needed when running experiments at 55°C. In the mean time, heavy diluting nitrogen (10 times of the reactor outlet gas at 25°C and 15 times at 55°C) was used to decrease the possible interferences of water vapor.

Instead of using nitrogen as carrier gas and air as diluting gas, only pure nitrogen was used. As shown in figure 4.2, results with nitrogen alone give an almost identical calibration line as that of those with air present. Therefore, air does not interfere with mercury detection.

Additional experiments with NO<sub>2</sub> and SO<sub>2</sub> mixed with mercury were conducted as well. Mercury concentration decreased steadily when the drying tube (contained Mg(ClO<sub>4</sub>)<sub>2</sub>) was used before the analyzer. When the drying tube was eliminated from the system, the calibration lines were the same as those of mercury with air or nitrogen. We concluded that NO<sub>2</sub> and SO<sub>2</sub> did not interfere with mercury analysis when the drying tube was eliminated. For consistency, the drying tube was not included in the apparatus for all subsequent experiments.

Later in February 1996, an experiment was designed to test the effect of SO<sub>2</sub> once again. The test was conducted under conditions similar to actual experiments (approximately the same relative humidity of the reactor outlet gas, heavy N<sub>2</sub> dilution after reactor outlet and water knock out flask). 97 ppb Hg in

N<sub>2</sub> bypassed the reactor first and a stable reading was obtained. While the gas stream still bypassed the reactor, 47 ppm SO<sub>2</sub> was added to the Hg-N<sub>2</sub> stream and the Hg-N<sub>2</sub> flow rate was adjusted to keep 97 ppb Hg in the mixture. The same steady state analyzer reading was obtained. After this, the SO<sub>2</sub> was shut off and the original Hg-N<sub>2</sub> stream was shifted to pass over distilled water inside the reactor. The same analyzer reading was obtained. Then 47 ppm SO<sub>2</sub> was added to the Hg-N<sub>2</sub> stream again and passed over distilled water. The same analyzer reading was obtained. After this, the same Hg-SO<sub>2</sub>-N<sub>2</sub> stream was shifted to bypass the reactor. The same analyzer reading was obtained. Then the same Hg-SO<sub>2</sub>-N<sub>2</sub> stream was shifted to pass over water again. The same analyzer reading was obtained. After this, SO<sub>2</sub> concentration was decreased to 23 ppm but Hg concentration was kept constant and the gas stream was passed over water, the same analyzer reading was obtained. The gas stream was bypassed again with and without SO<sub>2</sub>. The same analyzer reading was obtained in both cases. When "same analyzer reading was obtained", it means that the reading was within less than 4% error.

The effect of gas flow rate into the analyzer was also investigated. A fixed concentration of mercury vapor was fed into the analyzer and the steady state absorbance units and voltage were recorded. The flow rate of the mercury vapor was changed and different steady state absorbance units and voltage were recorded. The results are shown in figure 4.3. The mercury analyzer reading was proportional to the flow rate of the mercury vapor being fed through the analyzer. When flow rate was increased by a factor of 4.2, both the absorbance units and the voltage response increased by a factor of 1.1. In order to monitor the flow rate

and to keep a constant flow rate into the analyzer in the same experiment, a rotameter was connected to the outlet of the analyzer. The flow rate into the mercury analyzer was usually kept at 150-200 cc/min.

---

Figure 4.3 The dependence of mercury analyzer reading on gas flow rate passed through the analyzer.

---

#### 4.1.4 Summary

On the basis of above experimental results, the 10 mV full scale output port was chosen to be the analyzer output. To account for the effect of analyzer drifting, calibration was conducted both before and after the experiments. The calibration equation obtained from the above two calibration results assuming a

linear analyzer drift was used in data analyses. To minimize the interferences of water vapor, large nitrogen dilution ( 10 to 15 times of the reactor outlet gas flow rate ) and a water knock out flask were necessary to ensure reliable results.

## **4.2 LIQUID FILM MASS TRANSFER COEFFICIENT**

Mass transfer coefficients were measured in the stainless steel stirred tank reactor by McGuire (1990) using sulfur dioxide. Due to the unique characteristics of mercury, it was necessary to recalibrate the same reactor with mercury. The following calibration was conducted in the stainless steel reactor, not the new Teflon coated reactor. However, the same correlation was used for experiments conducted in the Teflon coated reactor later.

### **4.2.1 Mercury Desorption from Water without Reducing Agent at 25°C**

The objective of this experiment was to measure the liquid film mass transfer coefficient,  $k_{l, Hg}^o$ , by desorbing elemental mercury from water. Liquid mercury was put into a beaker with distilled water, stirred for 48 hours while being exposed to the ambient air. The clear mercury solution was then decanted into the stirred tank reactor. Nitrogen or air was flowed above this solution to desorb dissolved elemental mercury. If all the dissolved mercury was in the elemental form and the partial pressure of the desorbed mercury,  $P_{Hg, out}$ , was small so that it could be neglected, the slope of  $\ln(C_{Hg}/C_{Hg, initial})$  versus time should give the liquid film mass transfer coefficient,  $k_{l, Hg}^o$ . Here  $C_{Hg}$  is the concentration of mercury in liquid phase at time  $t$  and  $C_{Hg, initial}$  is the initial liquid phase mercury concentration.

Figure 4.4 gives the results of two mercury desorption experiments. 1.1 l/min air was used in one experiment while 0.2 l/min nitrogen was used in the other. The gas and liquid agitation speeds were approximately the same in these two experiments. The initial mercury concentration in the liquid phase  $C_{\text{Hg, initial}}$  was  $1 \times 10^{-4}$  M by flame atomic absorption spectrophotometer analysis. Since the solubility of liquid mercury in water is only  $3.05 \times 10^{-7}$  M without oxygen, there must be some oxidized forms of mercury present in the liquid phase. This was consistent with the fact that mercury solution was prepared in the presence of air. The measured initial mercury concentration  $C_{\text{Hg, initial}}$  was also close to the reported liquid mercury solubility data with the presence of oxygen.

Using the modified  $k^{\circ}_l$  value from  $\text{SO}_2$  data, the range of mercury flux, liquid phase driving force and total mercury in liquid phase can be obtained. The results are listed in table 4.1. The high end of the liquid phase driving force in one of the experiments (  $0.9 \mu\text{M}$  ) was two times larger than the solubility limit of liquid mercury at  $25^\circ\text{C}$  (  $0.3 \mu\text{M}$  ). This raised the possibility that dissolved oxidized mercury species were reduced to elemental mercury in the mass transfer boundary layer.

Table 4.1 Mercury desorption from distilled water without the presence of reducing agent at  $25^\circ\text{C}$ .

gas flow rate ( $\frac{\text{l}}{\text{min}}$ )	$n_g$ (rpm)	$n_l$ (rpm)	$N_{\text{Hg}}$ ( $\frac{\text{mole}}{\text{s-m}^2}$ ) $\times 10^9$	liquid phase driving force (M) $\times 10^7$	total Hg in liquid phase (M) $\times 10^4$
air 1.1	155	284	high 12.1	high 8.9	1.0

			low 2.9	low 2.3	-

\* The solubility of liquid mercury at  $25^\circ\text{C}$  in water without oxygen is  $3.05 \times 10^{-7}$  M

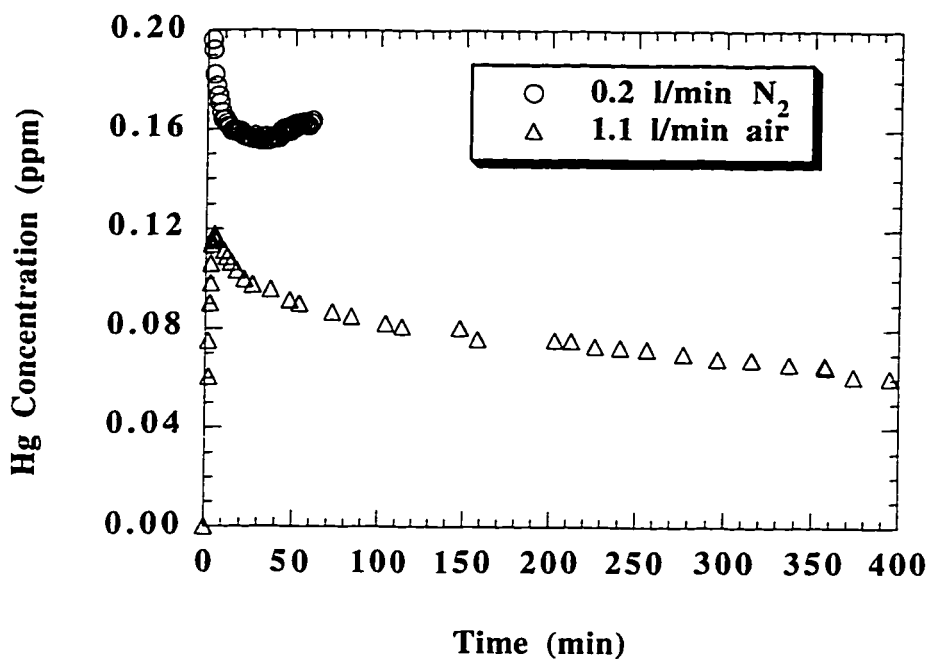

Figure 4.4 Mercury desorption from distilled water at 25°C. Either nitrogen or air was used as stripping gas. Gas and liquid phase agitation speeds were 136 and 267 rpm, respectively.

In order to ensure that only elemental mercury is present in the solution, mercury desorption from a reducing environment is necessary. In addition, pure nitrogen should be used as the stripping gas rather than air to further reduce the possibility of oxidation. A large stripping gas flow rate, such as 1 l/min, should be used to obtain a large liquid phase driving force and a large mercury flux.

## 4.2.2 Mercury Desorption from Water in the Presence of Reducing Agent at 25°C

### 4.2.2.1 Theoretical Basis

The mercury desorption method was improved by adding a small amount of  $\text{HgCl}_2$  to a  $\text{SnCl}_2\text{-H}_2\text{SO}_4$  reducing solution. The produced elemental mercury did not exceed its solubility limit. This ensures that all the mercury in the liquid phase exists in its elemental form. The liquid phase mass balance gives:

$$\frac{V dC_{\text{Hg}}}{dt} = -k_{\text{l, Hg}}^{\circ} A \left( C_{\text{Hg}} - \frac{P_{\text{Hg, out}}}{H_{\text{Hg}}} \right) \quad (4-1)$$

Assuming  $P_{\text{Hg, out}}$  is negligible compare to  $C_{\text{Hg}}$ , this leads to:

$$\frac{dC_{\text{Hg}}}{C_{\text{Hg}}} = -\frac{k_{\text{l, Hg}}^{\circ} A}{V} dt \quad (4-2)$$

Integration of the above differential equation results in:

$$C_{\text{Hg}} = C_{\text{Hg, initial}} \exp \left( -\frac{k_{\text{l, Hg}}^{\circ} A}{V} t \right) \quad (4-3)$$

From the gas phase mass balance:

$$G (P_{\text{Hg, out}} - P_{\text{Hg, in}}) = RT k_{\text{l, Hg}}^{\circ} A \left( C_{\text{Hg}} - \frac{P_{\text{Hg, out}}}{H_{\text{Hg}}} \right) \quad (4-4)$$

Assume  $C_{\text{Hg}} \gg \frac{P_{\text{Hg, out}}}{H_{\text{Hg}}}$  and the stripping nitrogen has no mercury in it so

that  $P_{\text{Hg, in}} = 0$ . The Combination of liquid and gas phase mass balance gives:

$$\ln P_{\text{Hg, out}} = \ln \left( \frac{RT C_{\text{initial}} k_{\text{l, Hg}}^{\circ} A}{G} \right) - \frac{k_{\text{l, Hg}}^{\circ} A}{V} t \quad (4-5)$$

From the plot of  $\ln P_{\text{Hg, out}}$  versus time, the liquid film mass transfer coefficient  $k_{\text{l, Hg}}^{\circ}$  can be obtained either from the slope or the intercept.

### 4.2.2.2 Experimental Procedure

Elemental mercury was produced by injecting a low concentration of  $\text{HgCl}_2$  into a strong reducing solution. The recommended reducing solution was 1%  $\text{SnCl}_2$ , 10%  $\text{H}_2\text{SO}_4$  and 1%  $\text{NaCl}$ . The resulted reducing solution is a turbid,

skim milk like mixture. Initial runs with this turbid solution did not give good results and  $k^o_l$  values obtained from these experiments were lower than those from clear solution experiments. This is not surprising since mercury might adsorb on the surface of suspended solids in the solution and the adsorption/desorption complicated the process. Clear reducing solution was obtained by filtering the solution using cellulose acetate membrane filter ( 0.2  $\mu\text{m}$  pore size, Micro Filtration Systems ).

In a typical experiment,  $10^{-7}$  M mercuric chloride was injected into fresh prepared reducing solution using a septum and a long needle well below the surface of the solution inside the reactor. The purpose of this procedure was to keep an undisturbed process during injection and prevent mercury loss at the time of  $\text{HgCl}_2$  injection. Before and during the addition of  $\text{HgCl}_2$ , pure nitrogen was continuously passed over the liquid phase and the liquid phase agitator was set at a very low speed. This should minimize the accumulation of reduced elemental mercury in the gas-liquid interface. After  $\text{HgCl}_2$  injection, the gas and liquid phase agitation speed were immediately adjusted to desired values. This moment was time zero. The gas phase outlet mercury concentration was then recorded continuously as the experiment proceeded.

#### **4.2.2.3      *Results and Discussion***

Figure 4.5 gives the results of the mercury desorption experiments. The slope of each experiment was obtained from the linear part of the data, usually those after the initial mercury accumulation periods. The resulting  $k^o_l$  values from the slope and the material balance are given in table 4.2. The total amount

of Hg desorbed was estimated by integrating the gas outlet concentration over time. As shown in table 4.2, the recovery of Hg was always less than 100% and varied from 7 to 80%.

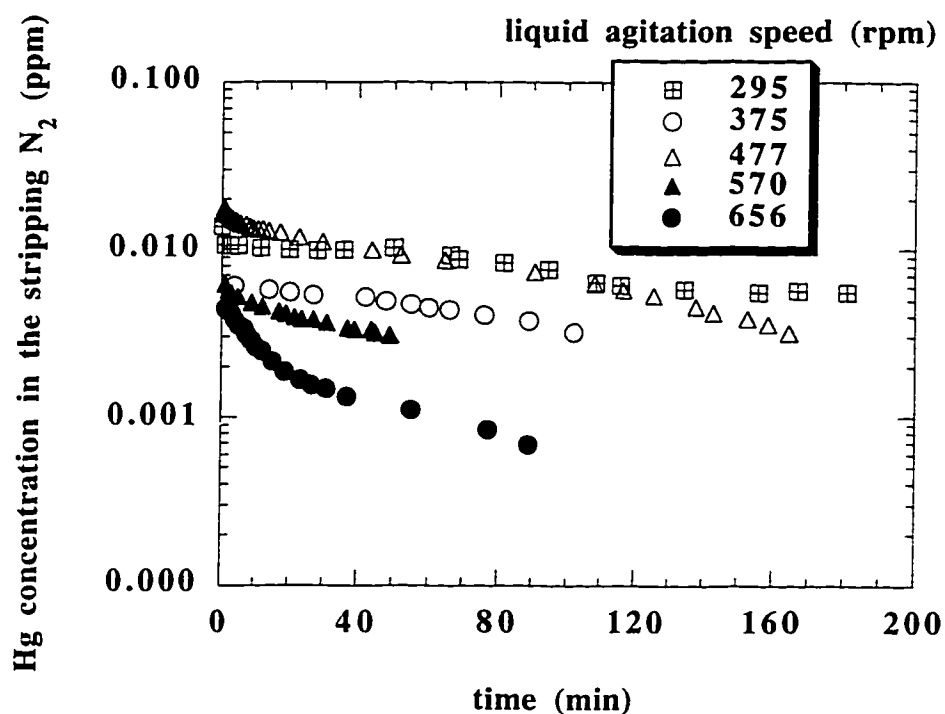

Figure 4.5 Hg desorption from water when  $10^{-7}$  M  $\text{HgCl}_2$  was injected into clear 0.05 M  $\text{SnCl}_2$ -1 M  $\text{H}_2\text{SO}_4$ -0.2 M  $\text{NaCl}$  at  $25^\circ\text{C}$ . Stripping  $\text{N}_2$  flow rate was 1 l/min.

Mercury desorption gave the following  $k_{l, \text{Hg}} - n_l$  correlation:

$$k_{l, \text{Hg}} = 2.42 \times 10^{-7} (n_l)^{0.73} \text{ m/sec} \quad (4-6)$$

Table 4.2 Hg desorption from water at 25°C when  $10^{-7}$  M  $\text{HgCl}_2$  was injected into filtered 1%  $\text{SnCl}_2$ -10%  $\text{H}_2\text{SO}_4$ -1%  $\text{NaCl}$  solution. Stripping  $\text{N}_2$  flow rate was 1 l/min.

T (°C)	$n_l$ (rpm)	length of experiment (min)	$k_{l, \text{Hg}}^{\circ}$ from slope $\left(\frac{\text{m}}{\text{s}}\right) \times 10^5$	Hg desorbed* (%)
24	295	181	1.64	80
26	375	102	1.74	37

26	570	49	2.51	18
26	656	89	2.90	7

\* Integration only accounted for the length of the experiments.

#### 4.2.3 $\text{CO}_2$ Desorption from Water at 25°C

The  $\text{CO}_2$  desorption method was developed to check the reliability of the previously described mercury desorption results. The advantage of using  $\text{CO}_2$  is that it is unlikely to adsorb on the solid metal surfaces, thus eliminating interferences that might be significant in mercury desorption measurements.

The theoretical basis is essentially the same as that for mercury desorption. The  $k_{l, \text{CO}_2}^{\circ}$  values were obtained from the plot of  $\ln P_{\text{CO}_2, \text{out}}$  versus time, where the following equation applies:

$$\ln P_{\text{CO}_2, \text{out}} = \ln \left( \frac{RT C_{\text{initial}} k_{l, \text{CO}_2}^{\circ} A}{G} \right) - \frac{k_{l, \text{CO}_2}^{\circ} A}{V} t \quad (4-7)$$

Aqueous  $\text{CO}_2$  was produced by injecting sodium carbonate solution into 10% sulfuric acid. A septum and a long needle well below the liquid surface were used to inject sodium carbonate. The initial injected 0.03 mM  $\text{Na}_2\text{CO}_3$  was too small to cause significant  $\text{CO}_2$  production. The highest  $\text{CO}_2$  concentration produced was around 20 ppm, which was in the noise range of the  $\text{CO}_2$  analyzer. The initial added  $\text{Na}_2\text{CO}_3$  was then increased to 6.5 mM. This concentration was below the solubility limit of  $\text{CO}_2$  at 1 atm.

By examining the raw data of two experiments with 6.5 mM Na<sub>2</sub>CO<sub>3</sub> injection, we found that the calibration of the CO<sub>2</sub> analyzer was not accurate due to the interference of water vapor. A wet calibration method was used instead. This was accomplished by feeding CO<sub>2</sub> into the reactor filled with 10% sulfuric acid to ensure the same amount of moisture contained in the outlet mercury as that of the actual desorption experiment. During the wet CO<sub>2</sub> analyzer calibration, the reactor outlet CO<sub>2</sub> concentration dropped immediately but increased gradually until a stable reading. This was expected since CO<sub>2</sub> dissolved in water initially and gradually saturated the water. A steady state analyzer reading was obtained when CO<sub>2</sub> absorption and desorption reached equilibrium.

A typical experiment started with the wet CO<sub>2</sub> analyzer calibration. Then 6.5 mM Na<sub>2</sub>CO<sub>3</sub> was injected in 10% sulfuric acid and the outlet CO<sub>2</sub> concentration was recorded continuously. Figure 4.6 gives the results of these experiments. A straight line can be easily identified in each plot. The  $k^o_l$  values obtained from the slope and the material balance are tabulated in table 4.3. Nearly 100% recovery of CO<sub>2</sub> was obtained. This contrasts with only 7 to 80% recovery in mercury desorption. The  $k^o_l$  values obtained from CO<sub>2</sub> desorption were converted to  $k^o_l$  of mercury by using

$$k^o_{l, Hg} = k^o_{l, CO_2} \sqrt{\frac{D_{Hg.H_2O}}{D_{CO_2.H_2O}}} \quad (4-8)$$

and the result is:

$$k^o_{l, Hg} = 1.93 \times 10^{-7} (n_l)^{0.72} \quad (4-9)$$

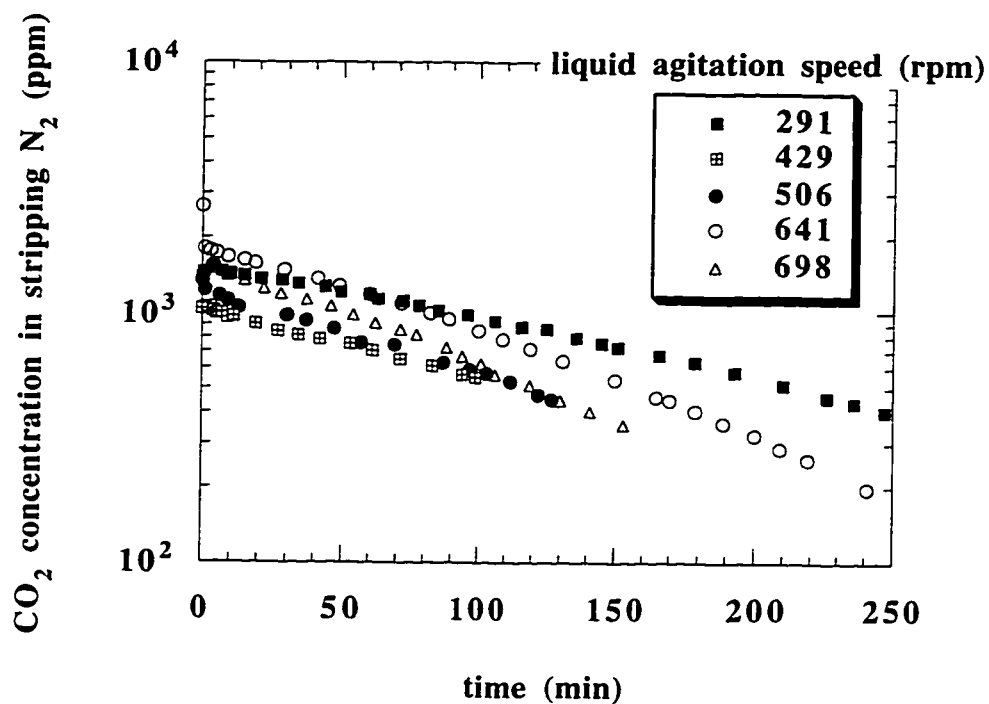

Figure 4.6  $\text{CO}_2$  desorption from water at 22-24°C when 6.5 mM  $\text{Na}_2\text{CO}_3$  was injected into 10% sulfuric acid. Stripping  $\text{N}_2$  flow rate was 1 l/min.

Table 4.3 Calibration of the liquid film mass transfer coefficient by  $\text{CO}_2$  desorption from water when initially injecting 6.5 mM  $\text{Na}_2\text{CO}_3$  into 10% sulfuric acid.

T (°C)	slope	nl (rpm)	$k^o_l$ from slope $(\frac{\text{m}}{\text{s}}) \times 10^5$	desorbed (%)
23	0.00529	291	1.198	121*
24	0.00655	429	1.483	101
22	0.00745	506	1.685	101
23	0.00912	641	2.065	117*
24	0.00949	698	2.147	100

\* Raw data based on dry bypass analyzer calibration were adjusted by the factor obtained from later wet analyzer calibration. This might also explain greater than 100% recovery.

#### 4.2.4 Comparison of $k_{l, \text{Hg}}$ Obtained from Different Methods

The  $k_{l, \text{SO}_2}$  values obtained from  $\text{SO}_2$  absorption (McGuire, 1990) were converted to  $k_{l, \text{Hg}}$  of mercury by using

$$k_{l, \text{Hg}} = k_{l, \text{SO}_2} \sqrt{\frac{D_{\text{Hg.H}_2\text{O}}}{D_{\text{SO}_2.\text{H}_2\text{O}}}} \quad (4-10)$$

The correlations of the liquid phase mass transfer coefficient of mercury,  $k_{l, \text{Hg}}$  with liquid phase agitation speed,  $n_l$  are listed below:

$$k_{l, \text{Hg}} = 1.93 \times 10^{-7} (n_l)^{0.72} \text{ m/sec} \quad (\text{from modified CO}_2 \text{ desorption}) \quad (4-11)$$

$$k_{l, \text{Hg}} = 2.42 \times 10^{-7} (n_l)^{0.73} \text{ m/sec} \quad (\text{from the slope of Hg desorption}) \quad (4-12)$$

$$k_{l, \text{Hg}} = 2.67 \times 10^{-7} (n_l)^{0.74} \text{ m/sec} \quad (\text{from modified SO}_2 \text{ absorption}) \quad (4-13)$$

Figure 4.7 gives the correlation of  $k_{l, \text{Hg}}$  with  $n_l$  from these three different methods. The slopes of these three lines are approximately the same. However, mercury desorption gave  $k_{l, \text{Hg}}$  values about 10% lower than those predicted from  $\text{SO}_2$  data and 20 % higher than those from  $\text{CO}_2$  desorption. From later permanganate results shown in chapter 5, it was clear that the stainless steel reactor was not appropriate for mercury experiments. The discrepancies might have been caused by the low reliability of the stainless steel reactor. Other possible explanations might include the errors associated with the estimated mercury diffusion coefficient in water, or the reactor characteristics might have been changed since those  $\text{SO}_2$  measurements were made.

In all following chapters, we used  $k_{l, \text{Hg}}$  values from mercury desorption, that is:

$$k_{l, \text{Hg}} = 2.42 \times 10^{-7} (n_l)^{0.73} \text{ m/sec} \quad (4-14)$$

#### 4.2.5 Liquid Film Mass Transfer Coefficient of mercury, $k_{l, \text{Hg}}^{\circ}$ at 55°C

The same factor was used as that measured by McGuire to modify  $k_{l, \text{Hg}}^{\circ}$  at 25°C to obtain  $k_{l, \text{Hg}}^{\circ}$  at 55°C. The correlation is:

$$k_{l, \text{Hg}}^{\circ} = 7.64 \times 10^{-7} (n_l)^{0.64} \text{ m/sec (55°C)} \quad (4-15)$$

Figure 4.7 Comparison of liquid film mass transfer coefficient of mercury obtained from different methods at 25°C.

#### 4.3 GAS FILM MASS TRANSFER COEFFICIENT CALIBRATION

Mercury absorption into concentrated permanganate was used to calibrate the gas film mass transfer coefficient of mercury,  $k_{g, \text{Hg}}$ . Detailed description can be found in chapter 5.

## **Chapter 5 Mercury Absorption in Aqueous Permanganate**

Aqueous acidic permanganate is known to be an effective solvent for elemental Hg vapor (Monkman et al., 1956; Hara, 1975). EPA method 29 specifies permanganate as the scrubbing solution for determination of elemental mercury in gas streams (Environmental Protection Agency, 1992). Permanganate has been used to collect mercury in flue gas field sampling procedures (Shendrikar et al., 1984). Even though permanganate is an expensive reagent, it is effective at low concentration for mercury removal, so it may be commercially useful for air pollution control or removal of mercury from other gases. No previous work was found giving the rate of reaction of permanganate with mercury. Therefore, the objective of this study was to quantify the kinetics in a well-characterized gas liquid contactor.

### **5.1 EXPERIMENTAL METHOD**

All experiments were performed in the well-characterized stirred cell reactor described in Chapter 3. The stainless steel reactor was used initially. Figure 5.1 gives the results of mercury absorption in  $\text{KMnO}_4$  in the stainless steel reactor. Most of the permanganate decomposed within three hours when initial injected permanganate did not exceed 3 mM. Bubbles were observed rising from the surface of the stainless steel baffles inside the reactor. It was later speculated that permanganate oxidized some of the iron in the reactor parts. The produced  $\text{Mn}^{2+}$  expedited permanganate decomposition. Data analysis of the figure 5.1 results gave a complicated second order dependence on mercury with scattered

data. It was under these circumstances that we decided to build a new Teflon coated reactor. With the new Teflon coated reactor, permanganate did not degrade under the same conditions as those of the old reactor. Data analysis gave reproducible, reasonable kinetics, as will be shown in detail later in this chapter.

Figure 5.1 Hg absorption in  $\text{KMnO}_4$ -1.8M  $\text{H}_2\text{SO}_4$  at 25°C in the old stainless steel reactor. The inlet mercury was 0.02 ppm. Total Hg- $\text{N}_2$  flow rate was 1 l/min.

The liquid film mass transfer coefficient,  $k_{\text{f}, \text{Hg}}$ , was determined by mercury and  $\text{CO}_2$  desorption, as described in detail in chapter 4. The gas film mass transfer coefficient,  $k_{\text{g}, \text{Hg}}$  was determined by mercury absorption into concentrated permanganate solution.

A stock solution of 0.1 M potassium permanganate was prepared from  $\text{KMnO}_4$  solid (EM Science), standardized by  $\text{Na}_2\text{C}_2\text{O}_4$  (Baker Analyzed Reagent) titration and stored in a brown bottle. Before titration, several drops of concentrated sulfuric acid was added to the permanganate sample to bring the solution acidity to 0.5-1 M and the solution was heated to 75-85°C. The sample was immediately titrated with 0.6-40 mM sodium oxalate depending on the initial concentration of  $\text{KMnO}_4$ . Usually  $\text{KMnO}_4$  served as a self indicator. If the sample solution was too dilute, several drops of 0.5 mM ferroin (indicator) were added to the solution. At the endpoint the solution color turned from pale blue to red (Harris, 1987).

1.8 M sulfuric acid solution was prepared by weighing a certain amount of concentrated sulfuric acid (EM Science) and diluted with distilled water to a desired volume.

In a typical experiment, 1.06 liters of 1.8 M sulfuric acid was put into the reactor while elemental mercury in nitrogen was bypassed the reactor. After the mercury analyzer gave a stable reading, the mercury stream was passed over 1.8 M sulfuric acid inside the reactor. This was the wet analyzer calibration. Again after the analyzer gave a stable reading, known amounts of the above permanganate solution or freshly prepared diluted permanganate solutions were sequentially injected into 1.8 M sulfuric acid using a syringe with a long needle. The outlet elemental mercury concentration was analyzed continuously and recorded by the strip chart recorder (Soltec Model 1242).

The rate of mercury absorption was calculated from the gas phase material balance. A four-point calibration was performed before and after each run to

account for the effect of base line drifting of the mercury analyzer.  $\text{MnO}_4^-$  addition to the liquid phase was determined by weighing the syringe before and after the injection.

## 5.2 MASS TRANSFER WITH SIMULTANEOUS CHEMICAL REACTION

The rate of reaction between elemental mercury vapor and  $\text{KMnO}_4$  is given by the mechanism:

$$\text{reaction rate} = k_2 [\text{Hg}] [\text{MnO}_4^-] \quad (5-2)$$

Using surface renewal theory (Danckwerts, 1970), the flux of mercury,  $N_{\text{Hg}}$ , should be given by:

$$N_{\text{Hg}} = \frac{P_{\text{Hgi}}}{H_{\text{Hg}}} \sqrt{k_2 [\text{MnO}_4^-]_i D_{\text{Hg-H}_2\text{O}}} \quad (5-3)$$

where:

$$P_{\text{Hgi}} = P_{\text{Hgb}} - \frac{N_{\text{Hg}}}{k_g} \quad (\text{significant}) \quad (5-4)$$

$$[\text{MnO}_4^-]_i = [\text{MnO}_4^-]_b - \frac{N_{\text{Hg}}}{k_{l,\text{MnO}_4^-}} \quad (\text{negligible}) \quad (5-5)$$

The value of  $k_{l,\text{Hg}}^o$  obtained from mercury desorption experiments in an identical reactor ( old stainless steel reactor ) was modified to give  $k_{l,\text{MnO}_4^-}^o$  :

$$k_{l,\text{MnO}_4^-}^o = k_{l,\text{Hg}}^o \sqrt{\frac{D_{\text{MnO}_4^- - \text{H}_2\text{O}}}{D_{\text{Hg-H}_2\text{O}}}} \quad (5-6)$$

The value of  $k_{g,\text{Hg}}$  is provided in detail in the next section. All physical constants used in the calculation are tabulated in table 5.1.

Table 5.1 Physical properties of Hg and MnO<sub>4</sub><sup>-</sup>.

	25°C	55°C
$D_{\text{Hg-H}_2\text{O}}^{\text{a}}$ (cm <sup>2</sup> sec <sup>-1</sup> )	$1.19 \times 10^{-5}$	$2.21 \times 10^{-5}$

### 5.3 RESULTS AND DISCUSSION

Figure 5.2 gives the experimental results for mercury absorption in permanganate. At 2.3 mM KMnO<sub>4</sub>, the mercury removal is practically the same as with 0.6 mM KMnO<sub>4</sub>. This indicates that the absorption of mercury into 2.3 mM KMnO<sub>4</sub> is gas phase controlled. This leads to the measurement of the gas film mass transfer coefficient. 3 mM KMnO<sub>4</sub> was injected into 1.8 M sulfuric acid with a fixed gas and liquid phase agitation speed. Mercury absorption was observed immediately. After steady state absorption was achieved, the gas agitation speed was increased and a different mercury absorption rate was observed. This process was repeated several times.  $k_{\text{g}}$  can be calculated from:

$$k_{\text{g}} = \frac{N_{\text{Hg}}}{P_{\text{Hg, out}}} \quad (5-7)$$

The results are given in table 5.2 and figure 5.3. The obtained gas phase mass transfer coefficient of mercury in this reactor (Teflon coated) is:

$$k_{\text{g, Hg}} A = 2.784 \times 10^{-4} (n_{\text{g}})^{0.38} \quad (5-8)$$

These  $k_{g, \text{Hg}}$  A values are smaller than those measured by McGuire with  $\text{SO}_2$  absorption into NaOH solution in an identical reactor ( old stainless steel reactor ) (McGuire, 1990), as shown in table 5.2 and figure 5.3. One explanation could be unknown differences between the current Teflon-coated reactor and the earlier stainless steel reactor. McGuire showed that  $k_g A$  is independent of temperature from 25 to 55°C. We used the same  $k_{g, \text{Hg}}$  A correlation for both 25 and 55°C.

Figure 5.2 Effect of  $\text{KMnO}_4$  on mercury removal during mercury absorption in  $\text{KMnO}_4$ -1.8M  $\text{H}_2\text{SO}_4$  solution at 25°C. The inlet mercury was 0.097 ppm, total  $\text{Hg-N}_2$  flow rate was 1 l/min.

Table 5.2 Calibration of gas film mass transfer coefficient by mercury absorption in 3 mM KMnO<sub>4</sub>-1.8 M H<sub>2</sub>SO<sub>4</sub> solution at 25°C. Hg<sub>in</sub> was 9.9x10<sup>-8</sup> atm and total Hg-N<sub>2</sub> flow rate was 1 l/min.

P <sub>Hgb</sub> x 10 <sup>8</sup> (atm)	n <sub>g</sub> (rpm)	k <sub>g</sub> A x 10 <sup>3</sup> (mole sec <sup>-1</sup> atm <sup>-1</sup> )

1.57	925	3.68	8.89

\* The values of k<sub>g</sub>A<sub>Hg</sub> were obtained from the values of k<sub>g</sub>A<sub>SO<sub>2</sub></sub> measured by McGuire (1990), corrected using  $k_{gA,Hg} = k_{gA,SO_2} \sqrt{\frac{D_{Hg-N_2}}{D_{SO_2-N_2}}}$ , where D<sub>Hg-N<sub>2</sub></sub> = 0.126 cm<sup>2</sup>sec<sup>-1</sup> (Nakayama, 1968) and D<sub>SO<sub>2</sub>-N<sub>2</sub></sub> = 0.130 cm<sup>2</sup>sec<sup>-1</sup> (Marrero and Mason, 1972) at 25°C.

Gas phase control can be further illustrated in figure 5.4. With 3.7 mM KMnO<sub>4</sub>, which was considered gas phase controlled, changes in gas agitation speed resulted in dramatic changes in mercury absorption rate. On the other hand, with 0.035 mM KMnO<sub>4</sub>, variation of the gas or liquid agitation speed did not cause a significant change in absorption rate. At 0.035 mM KMnO<sub>4</sub>, absorption was controlled by fast reaction near the gas-liquid interface and not by gas film diffusion.

Table 5.3 gives the results of mercury absorption into different concentrations of KMnO<sub>4</sub>. The detailed results can be found in appendix C. It is obvious that mercury removal is responsive to the amount of MnO<sub>4</sub><sup>-</sup> present in the solution. Figure 5.5 gives the dependence of normalized flux,  $\frac{N_{Hg}}{P_{Hgi}}$ , on the interfacial permanganate concentration [MnO<sub>4</sub><sup>-</sup>]<sub>i</sub>. These results are consistent with a reaction between Hg and MnO<sub>4</sub><sup>-</sup> that is first order in MnO<sub>4</sub><sup>-</sup>. For both 0.02

and 0.1 ppm inlet mercury, all data were fit with one line, as shown in figure 5.5. This indicates that the reaction is first order in Hg. The average value of the second order rate constant,  $k_2$ , is  $(1.6 \pm 0.2) \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  at  $25^\circ\text{C}$  and  $(12.6 \pm 5.3) \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  at  $55^\circ\text{C}$  at a 95% confidence level. Figure 5.6 gives the  $k_2$  values at 25 and  $55^\circ\text{C}$ . The experimental data for  $k_2$  were correlated with the following expression:

$$k_2 = 1.018 \times 10^{17} \exp\left(\frac{-6730}{T}\right) \quad (5-9)$$

The activation energy was calculated to be 56.0 kJ/mole (13.4 kcal/mole).

Figure 5.3 Comparison of gas film mass transfer coefficient of mercury obtained in two reactors using different methods.  $kgA_{\text{SO}_2}$  from McGuire, 1990 was corrected by  $kgA_{\text{Hg}} = kgA_{\text{SO}_2} \sqrt{\frac{D_{\text{Hg-N}_2}}{D_{\text{SO}_2\text{-N}_2}}}$ .

Figure 5.4 Effect of agitation speed on mercury removal during Hg absorption in  $\text{KMnO}_4/1.8\text{M H}_2\text{SO}_4$  solution at  $25^\circ\text{C}$ . The inlet mercury was 0.097 ppm, total  $\text{Hg/N}_2$  flow rate was 1 l/min.  $n_g$  was gas phase agitation speed and  $n_l$  was liquid phase agitation speed.

Table 5.3 The effect of  $\text{KMnO}_4$  during mercury absorption in  $\text{KMnO}_4$  and 1.8 M  $\text{H}_2\text{SO}_4$  solution. Total Hg- $\text{N}_2$  flow rate was 1 l/min.

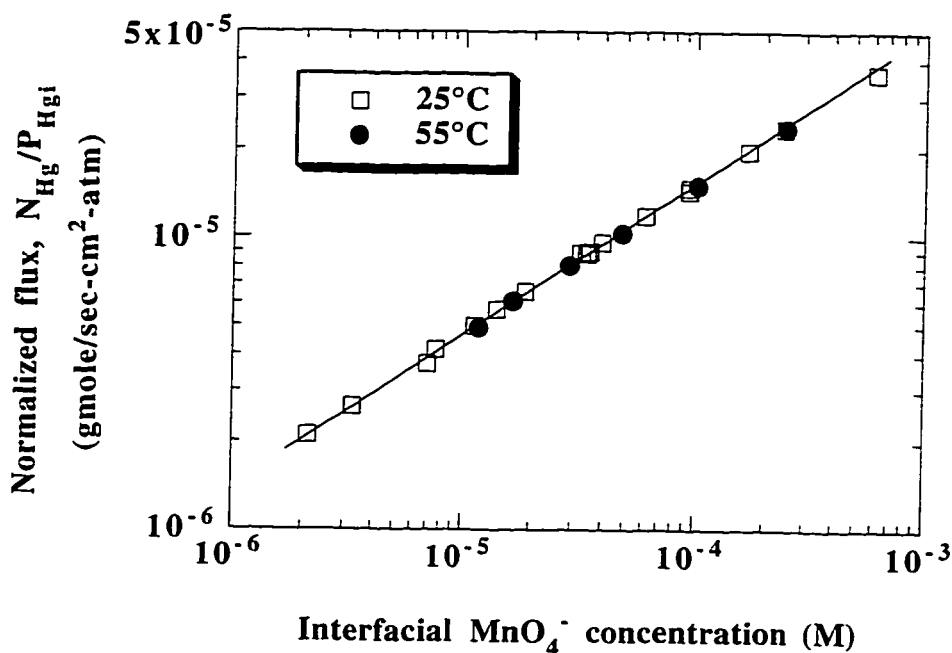

Figure 5.5 The dependence of normalized flux on  $[\text{MnO}_4^-]_i$  during mercury absorption in  $\text{KMnO}_4$ -1.8 M  $\text{H}_2\text{SO}_4$ . Total  $\text{Hg}/\text{N}_2$  flow rate was 1 l/min.

Other investigators studied the kinetics of  $\text{MnO}_4^-$  reaction with other reagents. Table 5.4 shows that the rate of permanganate reaction with mercury is faster than most reagents, but slower than reaction with hydrated electrons. The second order reaction of elemental mercury and ozone was also reported with a rate constant of  $4.7 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  (Munthe, 1992), which was in the same order of magnitude but faster than mercury reaction with permanganate.

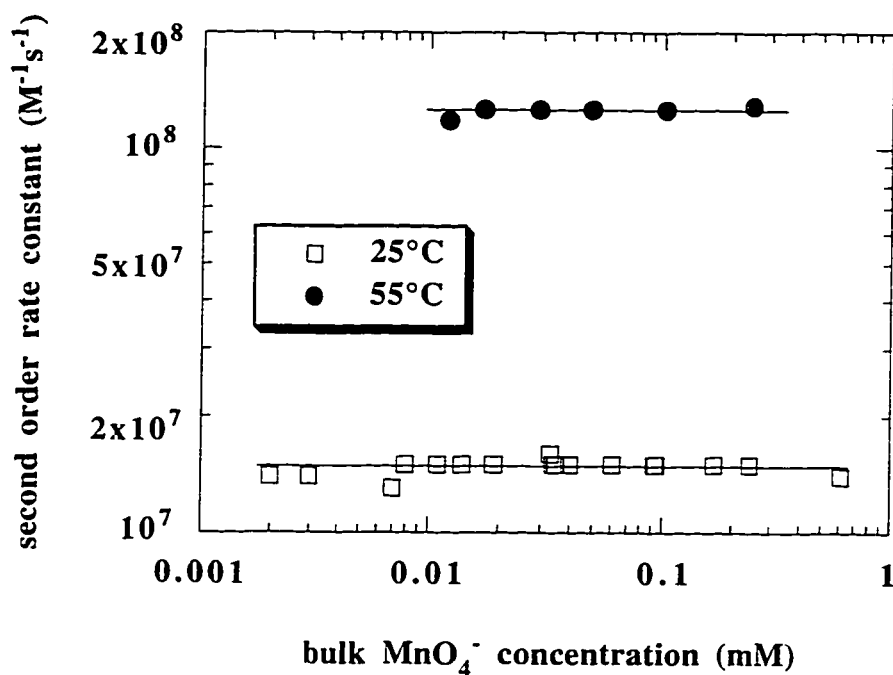

Figure 5.6 Reaction kinetics of mercury absorption in  $\text{KMnO}_4/1.8 \text{ M H}_2\text{SO}_4$  at 25 and 55°C. Total Hg- $\text{N}_2$  flow rate was 1 l/min.

Figure 5.7 The effect of  $\text{Mn}^{2+}$  on permanganate decomposition during mercury absorption in  $3.3 \times 10^{-5} \text{ M KMnO}_4 / 1.8 \text{ M H}_2\text{SO}_4$  at  $25^\circ\text{C}$ . The inlet mercury was 0.097 ppm, total  $\text{Hg}/\text{N}_2$  flow rate was 1 l/min.

---

The effect of  $\text{MnSO}_4$  was investigated as well. Figure 5.7 indicates that 4.3 mM  $\text{MnSO}_4$  was adequate to seriously weaken mercury absorption in 0.03 mM  $\text{KMnO}_4$ . In the case of figure 5.7, the addition of 4.3 mM  $\text{MnSO}_4$  decreased mercury removal from 95% to 10%.

## **Chapter 6 Mercury Absorption in Aqueous Oxidants Catalyzed by Mercury(II)**

Elemental mercury was absorbed in  $\text{HgCl}_2$  based aqueous solutions with  $\text{HgCl}_2$ -water as a base case for comparison purposes. The effects of strong acid, oxidants, salts, buffer solution and some combinations of them were investigated. The presence of  $\text{HNO}_3$  or  $\text{H}_2\text{SO}_4$  greatly enhanced mercury absorption. However,  $\text{HCl}$  inhibited mercury absorption. The addition of 0.1 M  $\text{H}_2\text{O}_2$  to 0.8 M  $\text{HNO}_3$  absorbed much more mercury than that of only with 0.8 M  $\text{HNO}_3$ . Both  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{K}_2\text{Cr}_2\text{O}_7$ - $\text{HNO}_3$  enhanced mercury absorption and the positive effect of adding  $\text{HNO}_3$  was more apparent than that of adding  $\text{K}_2\text{Cr}_2\text{O}_7$ .  $\text{MnSO}_4$  only mildly enhanced mercury absorption. Other salts, such as  $\text{FeCl}_3$ ,  $\text{CaCl}_2$ ,  $\text{MgCl}_2$ ,  $\text{MgSO}_4$  and  $\text{NaCl}$ , inhibited mercury absorption in  $\text{HgCl}_2$ .  $\text{NaOH}$ -succinic acid buffer solution greatly enhanced while  $\text{NaHCO}_3/\text{NaOH}$  inhibited mercury absorption in  $\text{HgCl}_2$ .

### **6.1 PREVIOUS WORK**

EPA method 29 for field sampling of mercury specifies the use of hydrogen peroxide and nitric acid in the first impinger and permanganate and sulfuric acid in the following impinger (Environmental Protection Agency, 1992). This method assumes that hydrogen peroxide and nitric acid absorb divalent mercury but not elemental mercury vapor. However, results obtained at the High Sulfur Test Center indicate that the EPA mercury speciation method may not be reliable (Peterson et al., 1995). Several other researchers have indicated that the oxidation of elemental mercury by hydrogen peroxide may be important in the

atmospheric environment (Lindqvist et al., 1984; Brosset, 1987; Kobayashi, 1987).

More recently, a German company has commercialized a sulfur dioxide and mercury scrubbing process called MercOx (Parkinson, 1996). In their process, a 35% aqueous solution of hydrogen peroxide is sprayed into the flue gas. Elemental mercury is oxidized by hydrogen peroxide to Hg(II) and remains in the solution. In a parallel reaction, the water spray converts SO<sub>2</sub> to sulfuric acid. As a result, all gaseous pollutants are converted and trapped in the solution. Dissolved mercury is removed by ion exchange and the acids are neutralized to salts and precipitated gypsum. In recent pilot test treating 500 m<sup>3</sup>/hr of flue gas stream at a sludge incinerator, mercury concentrations were reduced from a few hundred µg/m<sup>3</sup> to 20 µg/m<sup>3</sup>, well below the 50 µg/m<sup>3</sup> German limit.

The combination of hydrogen peroxide and a polyvalent metal ion has also been suggested as a potential oxidizer for elemental mercury. Kobayashi (1987) studied the mixtures of hydrogen peroxide with thirteen metal ions (Fe<sup>3+</sup>, Mn<sup>2+</sup>, Zn<sup>2+</sup>, Pb<sup>2+</sup>, Cu<sup>2+</sup>, Co<sup>2+</sup>, Ni<sup>2+</sup>, Cd<sup>2+</sup>, Sb<sup>3+</sup>, Bi<sup>3+</sup>, VO<sub>3</sub><sup>-</sup>, Ca<sup>2+</sup> and Al<sup>3+</sup>). Among these, only Fe<sup>3+</sup> enhanced mercury absorption and the reaction was first order in hydrogen peroxide and Fe<sup>3+</sup>, respectively. Munthe and McElroy (1992), however, concluded that the reactions between aqueous elemental mercury and hydrogen peroxide, or Fe<sup>3+</sup>, or a mixture of the two, were not significant.

Other researchers have studied the effect of Hg<sup>++</sup> on elemental mercury removal. Qualitative results obtained by Morita et al. (1983) reported that the rate of mercury absorption increased with increasing Hg<sup>++</sup> concentration and with increasing oxidation potential of dichromate solutions in sulfuric acid. The

combination of  $\text{Hg}^{++}$  and dichromate absorbed mercury more efficiently than either component alone. Strong mercury absorption in  $\text{HgCl}_2/\text{H}_2\text{SO}_4$  was also observed (Morita et al., 1983). Allgulin (1974) found that solution containing mercury(II) ions ranging from 0.02 g/l to saturation and at least one anion selected from the group  $\text{Cl}^-$ ,  $\text{Br}^-$ ,  $\text{I}^-$  and  $\text{SO}_4^{2-}$  was effective for removing  $\text{Hg}^0$ .

The objective of this study was to investigate the role of  $\text{Hg}(\text{II})$  and other oxidants on elemental mercury absorption in a variety of aqueous solutions.

## **6.2 EXPERIMENTAL METHODS**

All experiments were performed in the well-characterized stirred cell reactor described in Chapter 3. In a typical experiment, mercury diluted with nitrogen (1 l/min) bypassed the reactor. After the mercury analyzer gave a stable reading, the  $\text{Hg-N}_2$  stream was shifted to flow above 0.8 M nitric acid or other background solution, such as other acid, buffer solution or water. Again after the analyzer reached a stable reading, a known amount of 30 wt% hydrogen peroxide solution or mercuric chloride solution prepared from solid was injected using a syringe with a long needle into the reactor and the outlet mercury concentration was recorded continuously by a strip chart recorder (Soltec Model 1242). Each active liquid phase ingredient was injected sequentially rather than mixed outside the reactor. Prior to each injection, the same amount of solution was extracted from the reactor to keep the final liquid volume constant during mercury absorption.

The reactor outlet gas was immediately diluted with nitrogen by a factor of 10 at 25°C and 15 at 55°C to minimize water vapor interference on mercury

analysis. A three-point calibration of the analyzer (cold vapor atomic absorption) was conducted both before and after the experiment. The mercury concentration obtained when the Hg-N<sub>2</sub> was passed over the background solution of the actual experiment was used as the inlet mercury concentration (wet calibration). The rate of mercury absorption was calculated from the gas phase material balance. The bulk hydrogen peroxide concentration was determined by titration with potassium iodide and certified 1 N sodium thiosulfate solution (Appendix D). HgCl<sub>2</sub> or other reagent additions to the liquid phase were determined by weighing the syringe before and after the injection. The specifications of the reagents used are listed in table 6.1.

### 6.3 DETERMINATION OF MASS TRANSFER CHARACTERISTICS AND PHYSICAL PROPERTIES OF MERCURY

The determination of the gas phase mass transfer coefficient,  $k_{g, \text{Hg}}$ , was discussed in chapter 4 and its value is listed in table 6.2. The value of the liquid phase mass transfer coefficient of Hg,  $k_{l, \text{Hg}}$ , obtained from mercury desorption experiments in an identical reactor, was modified to give  $k_{l, \text{Hg}^{++}}$  :

$$k_{l, \text{Hg}^{++}} = k_{l, \text{Hg}} \sqrt{\frac{D_{\text{Hg}^{++}-\text{H}_2\text{O}}}{D_{\text{Hg}-\text{H}_2\text{O}}}} \quad (6-1)$$

The portion of  $[\text{Hg(II)}]_b$  resulting from mercury absorption was obtained by integration of the gas phase material balance. The nominal concentration of injected mercuric chloride was used for the portion of  $[\text{Hg(II)}]_b$  resulting from mercuric chloride injections. All other physical constants used in the calculation are tabulated in table 6.2.

Table 6.2 Physical properties of Hg and  $\text{Hg}^{++}$ .

## 6.4 RESULTS AND DISCUSSION

### 6.4.1 Absorption in Mercury(II)

For most experiments the results are reported as normalized flux,  $K_g'$ , analogous to the overall gas phase mass transfer coefficient:

$$K_g' = \frac{N_{\text{Hg}}}{P_{\text{Hgi}}} \quad (6-2)$$

Figure 6.1 gives the results of two independent tests. With only distilled water in the liquid phase, injections of  $\text{HgCl}_2$  resulted in step decreases of the outlet mercury concentration.

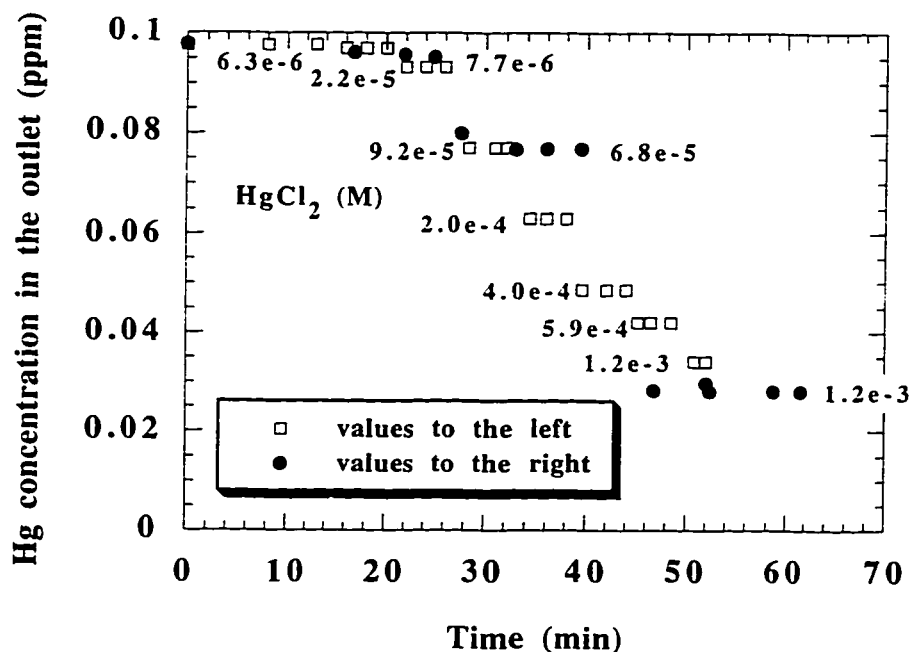

Figure 6.1 Hg absorption in distilled water with sequential  $\text{HgCl}_2$  injections at  $25^\circ\text{C}$ .  $\text{Hg-N}_2$  flow rate was 1 l/min. Solution pH was 4.82-4.14. Two different legends represent two independent runs under the same conditions.

The normalized flux,  $K_g'$ , increases with  $\text{HgCl}_2$  (figure 6.2). The log-log slope is greater than 0.5, indicating that without strict pH control, the apparent reaction between elemental mercury and mercuric chloride is not a simple second order reaction. Experimental results in table 6.3 indicate that the injection of more  $\text{HgCl}_2$  resulted in lower solution pH, as pH was reduced from 4.82 with 0.008 mM  $\text{HgCl}_2$  to 4.14 with 1 mM  $\text{HgCl}_2$ . Lower pH enhanced mercury removal by mercury(II), as shown in later sections.

Figure 6.2 Hg absorption in distilled water with sequential  $\text{HgCl}_2$  injections at 25°C. Hg- $\text{N}_2$  or Hg-air flow rate was 1 l/min. Solution pH was 4.82-4.14.

The effect of oxygen was investigated by mixing air with elemental mercury vapor instead of pure nitrogen. This resulted in 20% oxygen (by volume) in the gas phase. Known amounts of  $\text{HgCl}_2$  were injected into distilled water or other reagents and the results are given in figure 6.2. The presence of  $\text{O}_2$  in the gas phase makes no difference in Hg absorption in  $\text{Hg(II)}$  at  $25^\circ\text{C}$ .

Table 6.3 Mercury absorption in distilled water with sequential  $\text{HgCl}_2$  injections at  $25^\circ\text{C}$ . Total  $\text{Hg-N}_2$  or  $\text{Hg-air}$  flow rate was 1 l/min.  $P_{\text{Hg, in}}$  was  $1.02 \times 10^{-7}$  atm.  $k_{\text{g, Hg}}$  was  $0.39 \text{ gmol/s-atm-m}^2$ .  $k_{\text{l}^\circ, \text{Hg}^{++}}$  was  $2.2 \times 10^{-5} \text{ m/s}$  at  $25^\circ\text{C}$ .

#### 6.4.2 Absorption by Mercury (II) with the Addition of a Strong Acid or Buffer Solution

With a solution of a strong acid, we have found that the rate of reaction between elemental mercury vapor and mercuric chloride is given by the mechanism:

At constant pH the reaction rate is given with the second order rate constant,  $k_2$ :

$$\text{reaction rate} = k_2 [\text{Hg}] [\text{Hg(II)}] \quad (6-4)$$

Using approximate surface renewal theory (Danckwerts, 1970), the flux of elemental mercury,  $N_{\text{Hg}}$ , should be given by:

$$N_{\text{Hg}} = \frac{P_{\text{Hgi}}}{H_{\text{Hg}}} \sqrt{k_2 D_{\text{Hg-H}_2\text{O}}} [\text{Hg(II)}]_i \quad (6-5)$$

where:

$$P_{\text{Hgi}} = P_{\text{Hgb}} - \frac{N_{\text{Hg}}}{k_{\text{g.Hg}}} \quad (6-6)$$

$$[\text{Hg(II)}]_i = \frac{N_{\text{Hg}}}{k_{\text{l.Hg}^{++}}^{\circ}} + [\text{Hg(II)}]_b \quad (6-7)$$

#### 6.4.2.1 *Mercury Absorption in 0.8 M Nitric Acid*

Elemental mercury vapor was absorbed into 0.8 M nitric acid with sequential injection of mercuric chloride. Without any other oxidants, injection of mercuric chloride into 0.8 M nitric acid resulted in a step decrease in outlet mercury concentration. All of the experimental data are tabulated in table 6.4. Detailed results can be found in appendix E.

Figure 6.3 plots normalized flux,  $N_{\text{Hg}}/P_{\text{Hgi}}$  versus  $[\text{Hg(II)}]_i$ . The reaction is first order in Hg and Hg(II), respectively. The kinetic data at 55°C was difficult to obtain and unstable compared to that at 25°C. This was probably due to the difficulties encountered in cleaning the reactor from residual  $\text{HgCl}_2$  using the reducing agent  $\text{NaBH}_4$ . Sometimes, the reactor had to be first soaked in  $\text{NaBH}_4$  to get rid of the residual  $\text{HgCl}_2$  and then soaked in  $\text{H}_2\text{O}_2$  to neutralize the effect of  $\text{NaBH}_4$ . In contrast, soaking the reactor in  $\text{NaBH}_4$  before each experiment when conducting experiments at 25°C did not cause any difficulties and abnormal

results. As shown in figure 6.3, when the injected  $\text{HgCl}_2$  exceeded  $3 \times 10^{-5} \text{ M}$  at  $55^\circ\text{C}$ ,  $K_g'$  tended to flatten out. With  $\text{HgCl}_2$  less than  $3 \times 10^{-5} \text{ M}$ , the overall second order rate constant  $k_2$  is  $(7.8 \pm 2.1) \times 10^6 \text{ M}^{-1}\text{s}^{-1}$  at  $25^\circ\text{C}$  and  $(13.4 \pm 8.0) \times 10^6 \text{ M}^{-1}\text{s}^{-1}$  at  $55^\circ\text{C}$ . The experimental data for  $k_2$  were correlated with the following expression:

$$k_2 = 2.90 \times 10^9 \exp\left(\frac{-1765}{T}\right) \quad (6-8)$$

Table 6.4 Effect of  $\text{Hg(II)}$  on mercury absorption in  $0.8 \text{ M HNO}_3$ .  $P_{\text{Hg, in}}$  was  $1.0 \times 10^{-7} \text{ atm}$ .  $k_{g, \text{Hg}}$  was  $0.4 \text{ gmol/s-atm-m}^2$ .  $k_{l^\circ, \text{Hg}^{++}}$  was  $2.2 \times 10^{-5} \text{ m/s}$  at  $25^\circ\text{C}$  and  $4.0 \times 10^{-5} \text{ m/s}$  at  $55^\circ\text{C}$ .

\* represents data excluded from rate constant regression

At  $10^{-5}$  M Hg(II),  $K_g'$  was  $3.5 \times 10^{-6}$  with 0.8 M HNO<sub>3</sub> and  $1.6 \times 10^{-7}$   $\frac{\text{mole}}{\text{s-cm}^2\text{-atm}}$  without acid at 25°C, as shown in figures 6.2 and 6.3. This indicates

that the presence of HNO<sub>3</sub> greatly enhanced Hg absorption by mercury(II).

Figure 6.3 Hg absorption in 0.8 M HNO<sub>3</sub> with sequential HgCl<sub>2</sub> injection at 25 and 55°C. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

#### 6.4.2.2 Effects of HNO<sub>3</sub>, H<sub>2</sub>SO<sub>4</sub> and HCl

Figure 6.4 gives the results at 25°C when nitric acid, sulfuric acid or buffer solution was present in the solution. The base line is absorption in water without acid addition. Hg flux was significantly lower with 0.01 M HNO<sub>3</sub> and no acid than with 0.8 M HNO<sub>3</sub>. The difference was most significant at low Hg(II) and

diminished at higher Hg(II). For example, at  $10^{-5}$  M Hg(II), the normalized flux of mercury increased a factor of 32 with 0.8 M HNO<sub>3</sub> compared to that with HgCl<sub>2</sub> alone. While at  $10^{-3}$  M Hg(II), the normalized flux of mercury only increased a factor of 1.5.

Figure 6.4 The dependence of second order rate constant  $k_2$  on  $[\text{Hg(II)}]_i$  with various acids and buffers in the solution at 25°C.  $k_2$  was obtained from eqn (6-5). N<sub>2</sub> was in the gas phase unless otherwise indicated in the legends. Experiments with O<sub>2</sub> were with 20% (by volume) O<sub>2</sub>. Total Hg-N<sub>2</sub> or Hg-air flow rate was 1 l/min.

The effect of HNO<sub>3</sub> is apparent in comparison of mercury absorption in 0.01, 0.1 and 0.8 M HNO<sub>3</sub> with sequential HgCl<sub>2</sub> injection.  $k_2$  was lower in

0.01M HNO<sub>3</sub> than in 0.1 M HNO<sub>3</sub> at the same Hg(II) level. Figure 6.4 also shows that  $k_2$  in 0.01 M HNO<sub>3</sub> was greater than with no HNO<sub>3</sub> at the same level of Hg(II). However, there was very little increase in  $k_2$  when HNO<sub>3</sub> was increased from 0.1 M to 0.8 M. At high Hg(II), concentration differences in HNO<sub>3</sub> did not make much difference in  $k_2$ . The results of HNO<sub>3</sub> injections from  $8 \times 10^{-6}$  to 0.7 M indicate that at Hg(II) greater than 1 mM, increased Hg(II) was the primary reason of high mercury absorption compared to the increased HNO<sub>3</sub> acidity.

For the other acid systems studied, keeping a high and constant level of H<sup>+</sup> was essential to obtain an overall second order reaction between elemental mercury and Hg(II). When a high level of HNO<sub>3</sub> existed, injections of HgCl<sub>2</sub> did not change the solution pH significantly. However, when a small amount of HNO<sub>3</sub> was present, injections of HgCl<sub>2</sub> decreased the solution pH significantly.  $k_2$  increased as the injected amount of Hg(II) was increased. This was the effect of both increased Hg(II) and lower pH associated with increased HgCl<sub>2</sub>. This is the primary reason that  $k_2$  depend on Hg(II).

The effect of 0.8 M H<sub>2</sub>SO<sub>4</sub> on Hg absorption at 25°C is comparable to that of 0.8 M HNO<sub>3</sub>.

The effect of HCl was studied in a similar manner with only elemental mercury vapor and nitrogen in the gas. HgCl<sub>2</sub> was sequentially injected into 0.8 M HCl at 25°C to give  $10^{-6}$  to  $10^{-3}$  M HgCl<sub>2</sub>. The outlet Hg concentration exceeded the inlet Hg concentration and increased as the concentration of injected HgCl<sub>2</sub> increased. The same phenomenon was observed when 0.9 M HCl was used in another effort. This indicates that the presence of HCl in HgCl<sub>2</sub> not only

did not remove mercury but reduced some of the injected  $\text{HgCl}_2$  to elemental form.

$\text{HgCl}_2$  was sequentially injected into 0.9 M HCl with 20% oxygen in the gas phase. Although a finite amount of mercury removal was detected, the presence of HCl inhibited Hg absorption in  $\text{Hg(II)}$ , as shown in figure 6.4. However, in the absence of oxygen, the outlet Hg concentration exceeded the inlet Hg concentration and increased as the amount of injected  $\text{HgCl}_2$  increased.

#### **6.4.2.3      *Effect of NaOH-succinic acid buffer***

From the results with various degrees of  $\text{HNO}_3$  and  $\text{HgCl}_2$  in the solution, it seems that pH plays an important role. Thus a 0.01 M NaOH-0.01 M succinic acid buffer solution was used to keep a reasonably constant pH at 5.6 while subsequently injecting  $\text{HgCl}_2$ . The results are shown in figure 6.4.  $k_2$  was comparable to that with 0.8 M  $\text{HNO}_3$ , even though the buffer solution pH was much higher. This indicates that 0.01 M NaOH-0.01 M succinic acid buffer greatly enhances Hg absorption in  $\text{Hg(II)}$ . With 20% oxygen in the gas phase,  $k_2$  did not change significantly. This indicates that oxygen has negligible effect on Hg absorption in 0.01 M NaOH-0.01 M succinic acid buffer with sequential  $\text{HgCl}_2$  injection.

#### **6.4.2.4      *Effect of $\text{NaHCO}_3$ -NaOH buffer***

With only nitrogen and Hg in the gas phase,  $\text{NaHCO}_3$ -NaOH buffer was used to maintain the solution pH at 9.49-9.56.  $\text{HgCl}_2$  injections into  $\text{NaHCO}_3$ -NaOH buffer gave  $10^{-6}$  to  $10^{-3}$  M  $\text{Hg(II)}$ . The outlet Hg concentration increased as the amount of  $\text{HgCl}_2$  injected increased, as shown in table 6.5. For all the

HgCl<sub>2</sub> injections performed, the outlet Hg concentration exceeded the inlet Hg concentration. This indicates that the injected HgCl<sub>2</sub> was somehow reduced to elemental mercury and got stripped out of the solution.

The presence of 20% O<sub>2</sub> contributed to inhibiting the reduction of injected HgCl<sub>2</sub>, but not enough to cause Hg absorption. When the injected HgCl<sub>2</sub> was increased to a certain high value, such as 5.26x10<sup>-4</sup> M, 20% O<sub>2</sub> was no longer enough to prevent HgCl<sub>2</sub> from being reduced.

Table 6.5 The effect of oxygen on Hg absorption in NaHCO<sub>3</sub>-NaOH buffer solution at 25°C.

O <sub>2</sub>	HgCl <sub>2</sub> (M)	pH	Results
0	10 <sup>-6</sup>	9.56	Hg <sub>out</sub> > Hg <sub>in</sub>

20	2.17x10 <sup>-5</sup>	9.63	Hg <sub>out</sub> = Hg <sub>in</sub>
20	1.47x10 <sup>-4</sup>	9.61	Hg <sub>out</sub> = Hg <sub>in</sub>
20	5.26x10 <sup>-4</sup>	9.55	Hg <sub>out</sub> > Hg <sub>in</sub>

#### 6.4.3 Mercury Absorption in Hydrogen Peroxide and Nitric Acid

The rate of reaction between elemental mercury vapor and hydrogen peroxide is given by the mechanism:

Since the reaction product Hg(II) catalyses Hg absorption, the rate of reaction at constant pH with the third order rate constant,  $k_3$ , is given by:

$$\text{reaction rate} = k_3 [\text{Hg}] [\text{Hg(II)}] [\text{H}_2\text{O}_2] \quad (6-10)$$

Using surface renewal theory, the flux of elemental mercury,  $N_{\text{Hg}}$ , should be given by:

$$N_{\text{Hg}} = \frac{P_{\text{Hg}i}}{H_{\text{Hg}}} \sqrt{k_3 D_{\text{Hg-H}_2\text{O}} [\text{Hg(II)}]_i [\text{H}_2\text{O}_2]_i} \quad (6-11)$$

where:

$$P_{\text{Hgi}} = P_{\text{Hgb}} - \frac{N_{\text{Hg}}}{k_{\text{g,Hg}}} \quad (6-12)$$

$$[\text{H}_2\text{O}_2]_{\text{i}} \approx [\text{H}_2\text{O}_2]_{\text{b}} \quad (6-13)$$

$$[\text{Hg(II)}]_{\text{i}} = \frac{N_{\text{Hg}}}{k_{\text{l,Hg}}^{\circ}} + [\text{Hg(II)}]_{\text{b, initial injected}} + [\text{Hg(II)}]_{\text{absorbed}} \quad (6-14)$$

#### 6.4.3.1 Hydrogen Peroxide and 0.8 M Nitric Acid

Figure 6.5 gives typical responses when  $\text{H}_2\text{O}_2$  was injected into 0.8 M  $\text{HNO}_3$ . Hg outlet concentration dropped when additional  $\text{H}_2\text{O}_2$  was injected. It kept decreasing as absorption proceeded. This phenomenon can be explained by the accumulation of absorbed mercury species (mainly  $\text{Hg(II)}$ ). This assumption was verified by the results with  $\text{HgCl}_2$  injection shown in figure 6.6. Hg outlet concentration dropped dramatically when  $\text{HgCl}_2$  was injected. This indicates that  $\text{Hg(II)}$  catalyzes Hg absorption in  $\text{H}_2\text{O}_2$ - $\text{HNO}_3$ . The experimental data are tabulated in table 6.6.

Table 6.6  $\text{Hg}^{\circ}$  absorption in  $\text{H}_2\text{O}_2$ - $\text{Hg(II)}$  with 0.8M  $\text{HNO}_3$ . Total Hg- $\text{N}_2$  flow rate was 1 l/min.  $[\text{H}_2\text{O}_2]_{\text{b}}$  was determined by titration.

Figure 6.5 Hg absorption in H<sub>2</sub>O<sub>2</sub>/0.8 M HNO<sub>3</sub> at 25°C. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

---

---

Figure 6.6 Effect of  $H_2O_2$  and  $Hg(II)$  on Hg absorption in  $H_2O_2$ -0.8 M  $HNO_3$  at 25°C. Total Hg- $N_2$  flow rate was 1 l/min.

Figure 6.7 plots normalized flux,  $N_{Hg}/P_{Hgi}$  versus the product of  $[H_2O_2]_i$  and  $[Hg(II)]_i$ . The third order rate constant is  $(4.0 \pm 1.1) \times 10^8 \text{ M}^{-2}\text{s}^{-1}$  at 25°C and  $(88.8 \pm 9.9) \times 10^8 \text{ M}^{-2}\text{s}^{-1}$  at 55°C. The experimental data for  $k_3$  were correlated with the following expression:

$$k_3 = 2.13 \times 10^{23} \exp\left(\frac{-10110}{T}\right) \quad (6-15)$$

At our conditions 0.1 mM  $Hg(II)$  was sufficient to get 50% gas film resistance. Therefore, there may be specific conditions where elemental Hg will be absorbed by the first impinger in EPA method 29. As a result mercury

speciation by sequential absorption in peroxide and permanganate impingers may not give accurate or even reproducible results. In particular, the anomalous results on Hg injection at Shawnee (Peterson et al., 1995) may be explained as absorption of elemental mercury in the first  $\text{H}_2\text{O}_2$ - $\text{HNO}_3$  impinger.

Figure 6.7 The dependence of normalized mercury flux on the product of  $[\text{H}_2\text{O}_2]_i$  and  $[\text{Hg(II)}]_i$  during mercury absorption in  $\text{H}_2\text{O}_2/0.8 \text{ M HNO}_3$ . Total  $\text{Hg}/\text{N}_2$  flow rate was 1 l/min. The inlet Hg was tested at 20 and 98 ppb. The injected  $\text{H}_2\text{O}_2$  was varied between 0.1 and 1.0 M while  $\text{Hg}^{++}$  was varied between 0 and  $1.1 \times 10^{-4} \text{ M}$ .

#### 6.4.3.2 Effect of $\text{FeCl}_3$ in $\text{H}_2\text{O}_2$ and $\text{HNO}_3$

The effect of  $\text{Fe}^{3+}$  was investigated by adding  $\text{FeCl}_3$  to  $\text{H}_2\text{O}_2$ -0.8 M  $\text{HNO}_3$  with and without external  $\text{HgCl}_2$  injection. The results are given in figures 6.8 and 6.9.

Figure 6.8 The effect of  $\text{FeCl}_3$  on Hg absorption in  $\text{H}_2\text{O}_2$ -0.8 M  $\text{HNO}_3$  at  $25^\circ\text{C}$ . Total Hg- $\text{N}_2$  flow rate was 1 l/min.

Two injections of 0.1 and 0.25 M  $\text{H}_2\text{O}_2$  into 0.8 M  $\text{HNO}_3$  gave normal responses. However, four  $\text{FeCl}_3$  additions ranged from  $4.9 \times 10^{-4}$  to 0.02 M injected between and after the two  $\text{H}_2\text{O}_2$  injections gave no indication of additional mercury absorption. When 0.4 M  $\text{H}_2\text{O}_2$ , 0.1 mM  $\text{HgCl}_2$  and 0.8 M

$\text{HNO}_3$  were present in the solution, the injection of 0.2 M  $\text{FeCl}_3$  resulted in noticeable additional mercury removal. However, more  $\text{FeCl}_3$  injection of 0.4 M gave no additional mercury removal. In figure 6.9, the abnormal high mercury removal obtained from 0.8 M  $\text{HNO}_3$  might have just been the effects of residual  $\text{HgCl}_2$  from the last experiment. Nevertheless, it is still effective to see the net effect of individually injected reagent on Hg removal.

Figure 6.9 The effect of  $\text{FeCl}_3$  on Hg absorption in  $\text{H}_2\text{O}_2$ -0.8 M  $\text{HNO}_3$  with external  $\text{HgCl}_2$  injections at  $25^\circ\text{C}$ . Total  $\text{Hg-N}_2$  flow rate was 1 l/min.

#### 6.4.3.3 Effect of $\text{FeSO}_4$ in the presence of $\text{H}_2\text{O}_2$ and $\text{HNO}_3$

The effect of  $\text{Fe}^{2+}$  was investigated with 0.3 M  $\text{H}_2\text{O}_2$ -0.8 M  $\text{HNO}_3$  in the solution. As shown in figures 6.10 and 6.11, the injection of 0.004 to 0.2 M  $\text{FeSO}_4$  gave very little, if any, additional mercury removal.

Figure 6.10 The effect of  $\text{FeSO}_4$  on Hg absorption in  $\text{H}_2\text{O}_2$ -0.8 M  $\text{HNO}_3$  with external  $\text{HgCl}_2$  injection at 25°C. Total  $\text{Hg-N}_2$  flow rate was 1 l/min.

Figure 6.11 The effect of  $FeSO_4$  on Hg absorption in  $H_2O_2$ -0.8 M  $HNO_3$  with external  $HgCl_2$  injections at 25°C. Total Hg- $N_2$  flow rate was 1 l/min.

#### 6.4.3.4 Effect of $FeCl_3$ or $FeSO_4$ with only $H_2O_2$ present (no $HNO_3$ )

Pure water was put into the reactor and was heated and maintained at 55°C. After the bypassed Hg- $N_2$  reached steady state, a known amount of  $FeCl_3$  solution was injected into the reactor. After reaching steady state, another known amount of  $FeCl_3$  or  $H_2O_2$  was injected. Table 6.7 gives the results of this experiment. A phenomenon was observed for all of the last four  $H_2O_2$  injections that once  $H_2O_2$  was injected into the reactor, the outlet Hg concentration dropped

immediately and stabilized for a while, then it increased back to the inlet Hg concentration. One explanation could be that H<sub>2</sub>O<sub>2</sub> decomposed. Hg removal was evident only after H<sub>2</sub>O<sub>2</sub> and Fe<sup>3+</sup> concentrations exceeded certain limits.

Table 6.7 Hg absorption in H<sub>2</sub>O<sub>2</sub>-FeCl<sub>3</sub> at 55°C. The Hg-N<sub>2</sub> flow rate was 1 l/min and the inlet Hg was 97.5 ppb.

P <sub>Hgb</sub> ppb	$\frac{N_{Hg}}{P_{Hgi}} \times 10^7$ mole sec-cm <sup>2</sup> -atm	Reagent Injected	Concentration of Injected Reagent mM	Solution pH	k <sub>1</sub> $\frac{1}{\text{sec}}$
94.8	2.3	H <sub>2</sub> O	0.0	7.20	2
94.6	2.4	Fe <sup>3+</sup>	0.2	2.62	2
94.3	2.7	H <sub>2</sub> O <sub>2</sub>	0.4	2.70	3
92.9	3.9	Fe <sup>3+</sup>	1.9	1.56	8
92.8	4.0	Fe <sup>3+</sup>	8.8	0.92	8
77.2	21.5	H <sub>2</sub> O <sub>2</sub>	3.8	0.82	265
76.3	22.8	H <sub>2</sub> O <sub>2</sub>	4.2	0.74	298
70.6	31.9	H <sub>2</sub> O <sub>2</sub>	9.6	0.77	582
65.5	42.0	H <sub>2</sub> O <sub>2</sub>	45.9	0.75	1009

In another case, as shown in figure 6.12, the injection of 2 mM FeSO<sub>4</sub> to 0.1 M H<sub>2</sub>O<sub>2</sub> (no HNO<sub>3</sub>) resulted in very little additional Hg removal. External injections of HgCl<sub>2</sub> after this resulted in the usual step decrease of the outlet mercury.

Figure 6.12 The effects of  $\text{FeSO}_4$  and  $\text{HgCl}_2$  on Hg absorption in  $\text{H}_2\text{O}_2$  at  $25^\circ\text{C}$ . Total Hg/ $\text{N}_2$  flow rate was 1 l/min.

The above results indicate that the presence of  $\text{Fe}^{3+}$  or  $\text{Fe}^{2+}$  had no immediate effect on elemental mercury removal. In contrast, as little as  $10^{-6}$  M  $\text{HgCl}_2$  resulted in dramatic elemental mercury absorption.

In some of the experiments discussed before,  $\text{HNO}_3$  seemed to have Hg removal capability, although we speculated that those were not the effect of  $\text{HNO}_3$  but rather of residual  $\text{HgCl}_2$ . In order to test this hypothesis, an experiment was designed to test the effect of  $\text{HNO}_3$ . The results are given in figure 6.13. Three nitric acid injections of 0.1, 0.5 and 0.8 M did not change

outlet mercury concentration. After 0.012 mM  $\text{HgCl}_2$  was injected into the solution, subsequent 1.5 and 2.9 M  $\text{HNO}_3$  injections did not decrease the outlet  $\text{Hg}$  concentration further. Rather, the 2.9 M  $\text{HNO}_3$  injection increased the outlet  $\text{Hg}$  concentration. This was due to the decrease in  $\text{HgCl}_2$  concentration when  $\text{HNO}_3$  was injected into the solution. The above results prove that  $\text{HNO}_3$  alone has no effect on  $\text{Hg}$  removal. Thus the earlier results suggesting effects of  $\text{HNO}_3$  on  $\text{Hg}$  removal were merely the effects of residual  $\text{HgCl}_2$ . The residual  $\text{HgCl}_2$  effect was also evident in figure 6.9 with only water present.

Figure 6.13 The effect of  $\text{HNO}_3$  on  $\text{Hg}$  absorption in  $\text{H}_2\text{O}_2\text{-Hg(II)}$  at  $25^\circ\text{C}$ . Total  $\text{Hg-N}_2$  flow rate was 1 l/min.

#### 6.4.4 Absorption in Mercury(II) and Potassium Dichromate

The rate of reaction between elemental mercury vapor, Hg(II) and potassium dichromate in 0.8 M nitric acid is given by the mechanism:

When a fixed amount of  $\text{HNO}_3$  and  $\text{Cr}_2\text{O}_7^{2-}$  are present in the solution, the reaction rate can be written as:

$$\text{reaction rate} = k_2 [\text{Hg}] [\text{Hg(II)}] \quad (6-17)$$

where  $k_2$  is the pseudo-second-order rate constant.

Using surface renewal theory (Danckwerts, 1970), the flux of elemental mercury,  $N_{\text{Hg}}$ , should be given by:

$$N_{\text{Hg}} = \frac{P_{\text{Hgi}}}{H_{\text{Hg}}} \sqrt{k_2 D_{\text{Hg-H}_2\text{O}} [\text{Hg(II)}]_i} \quad (6-18)$$

in the case of constant  $\text{Cr}_2\text{O}_7^{2-}$  concentration.

In the above equations,

$$P_{\text{Hgi}} = P_{\text{Hgb}} - \frac{N_{\text{Hg}}}{k_{\text{g.Hg}}} \quad (6-19)$$

$$[\text{Cr}_2\text{O}_7^{2-}]_i \approx [\text{Cr}_2\text{O}_7^{2-}]_b \quad (6-20)$$

$$[\text{Hg(II)}]_i = [\text{Hg(II)}]_{b, \text{ initial injected}} + [\text{Hg(II)}]_{\text{absorbed}} - \frac{N_{\text{Hg}}}{k^{\circ} l_{\text{Hg}^{++}}} \quad (6-21)$$

Figure 6.14 gives typical results when  $\text{K}_2\text{Cr}_2\text{O}_7$  was used to absorb elemental mercury. The results show that  $\text{K}_2\text{Cr}_2\text{O}_7$  alone (without Hg(II) or  $\text{HNO}_3$ ) removes little (if any) Hg, even with  $\text{K}_2\text{Cr}_2\text{O}_7$  as high as 39 mM (not shown in figure 6.14 for this particular concentration). However, the combination of  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{HgCl}_2$  absorbs Hg more efficiently than either component alone, as shown in figures 6.15 and 6.16. The presence of  $\text{HNO}_3$  further enhanced Hg absorption. In addition, 0.8 M  $\text{HNO}_3$  has more positive effects on Hg removal

than increasing  $\text{K}_2\text{Cr}_2\text{O}_7$  alone. Solutions with all three components -  $\text{Hg}(\text{II})$ ,  $\text{HNO}_3$  and  $\text{K}_2\text{Cr}_2\text{O}_7$  were the most efficient for mercury absorption compared to those with only one or two components.

Figure 6.14 Hg absorption in  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{Hg}(\text{II})$  at  $25^\circ\text{C}$ . Total  $\text{Hg-N}_2$  flow rate was 1 l/min.

Of different combinations of  $\text{Hg}(\text{II})$ ,  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{HNO}_3$  tested, only  $\text{K}_2\text{Cr}_2\text{O}_7$ -0.8 M  $\text{HNO}_3$  with sequential  $\text{HgCl}_2$  injections exhibited a simple pseudo-second order reaction behavior. The data are tabulated in table 6.8. The pseudo-second order rate constant was  $1.4 \times 10^7 \text{ M}^{-1}\text{s}^{-1}$  at  $25^\circ\text{C}$ .

Figure 6.15 The effect of  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{HNO}_3$  on Hg absorption in Hg(II) at 25°C. Total Hg- $\text{N}_2$  flow rate was 1 l/min. Legends indicate the initial concentrations of  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{HNO}_3$ , respectively.

---

Table 6.8 Mercury absorption in  $K_2Cr_2O_7$ -0.8 M  $HNO_3$  with sequential  $HgCl_2$  injections at 25°C. Total  $Hg$ - $N_2$  flow rate was 1 l/min. The inlet mercury was 97.6 ppb. Solution pH ranged from 0.37 to 0.47.  $k_{g,Hg}$  was 0.4 gmol/s-atm- $m^2$ .  $k_{l^\circ,Hg^{++}}$  was  $2.2 \times 10^{-5}$  m/s.  $k_2$  is the pseudo-second order rate constant with a constant  $K_2Cr_2O_7$  concentration of 32.3 mM.

$P_{Hg, b}$ (ppb)	$[Hg(II)]_i$ $\times 10^5$ (M)	$N_{Hg}$ $\times 10^9$ ( $\frac{mole}{s \cdot m^2}$ )	$k_2$ $\times 10^{-7}$ ( $\frac{1}{M \cdot s}$ )
73.3	0.4	2.2	1.5
66.9	0.9	2.7	1.4
60.8	1.8	3.3	1.3
48.1	6.1	4.4	1.4
37.2	14.7	5.4	2.1
32.4	33.0	5.8	1.9

Figure 6.16 The effect of  $K_2Cr_2O_7$  and  $HNO_3$  on Hg absorption at 25°C.  $k_2$  was obtained from equation (6-18). Legends indicate the initial concentrations of  $K_2Cr_2O_7$  and  $HNO_3$ , respectively.

#### 6.4.5 Mercury Absorption in Mercury(II) and Manganese(II) Sulfate

The rate of reaction between elemental mercury vapor, Hg(II) and manganese(II) sulfate is given by the mechanism:

The rate of reaction is:

$$\text{reaction rate} = k_3 [\text{Hg}] [\text{Hg(II)}] [\text{Mn(II)}] \quad (6-23)$$

Using surface renewal theory (Danckwerts, 1970), the flux of elemental mercury,  $N_{\text{Hg}}$ , should be given by:

$$N_{\text{Hg}} = \frac{P_{\text{Hgi}}}{H_{\text{Hg}}} \sqrt{k_3 D_{\text{Hg-H}_2\text{O}} [\text{Hg(II)}]_i [\text{Mn(II)}]_i} \quad (6-24)$$

where:

$$P_{\text{Hgi}} = P_{\text{Hgb}} - \frac{N_{\text{Hg}}}{k_{g,\text{Hg}}} \quad (6-25)$$

$$[\text{Mn(II)}]_i \approx [\text{Mn(II)}]_b \quad (6-26)$$

$$[\text{Hg(II)}]_i = [\text{Hg(II)}]_b - \frac{N_{\text{Hg}}}{k^{\circ}_{l,\text{Hg}^{++}}} + [\text{Hg(II)}]_{\text{absorbed}} \quad (6-27)$$

If  $[\text{Hg(II)}]_b \gg [\text{Hg(II)}]_{\text{absorbed}}$ , then:

$$[\text{Hg(II)}]_i = [\text{Hg(II)}]_b - \frac{N_{\text{Hg}}}{k^{\circ}_{l,\text{Hg}^{++}}} \quad (6-28)$$

Figure 6.17 gives the results of mercury absorption in distilled water with sequential  $\text{HgCl}_2$  and  $\text{MnSO}_4$  injections at 25°C. No nitric acid or other reagent was present in the solution. The additions of  $\text{MnSO}_4$  enhanced mercury absorption in  $\text{Hg(II)}$ . However, the enhancement was not significant since substantial amounts of  $\text{MnSO}_4$  were needed.

Quantitative results are listed in table 6.9. At  $\text{MnSO}_4$  less than 0.22 M, a third order rate constant of  $4.4 \times 10^7 \text{ M}^{-2}\text{s}^{-1}$  was obtained. A rate constant of  $3.3\text{--}3.9 \times 10^7 \text{ M}^{-2}\text{s}^{-1}$  was obtained for  $\text{MnSO}_4$  greater than 0.23 M.

Table 6.9 Effect of Hg(II) and Mn(II) on mercury absorption in HgCl<sub>2</sub>-MnSO<sub>4</sub> at 25°C. Total Hg-N<sub>2</sub> flow rate was 1 l/min. The inlet Hg was 97.7 ppb.  $k_{g,Hg}$  was 0.4 gmol/s-atm-m<sup>2</sup>.  $k_{l^o,Hg^{++}}$  was 2.2x10<sup>-5</sup> m/s.

$P_{Hg, b}$ (ppb)	$N_{Hg}$ $\times 10^9$ ( $\frac{\text{mole}}{\text{s-m}^2}$ )	$[Hg(II)]_b$ $\times 10^5$ (M)	$[Mn(II)]_b$ (M)	pH	$k_3$ $\times 10^{-7}$ ( $\frac{1}{\text{M}^2\text{-s}}$ )

\* represents data excluded from rate constant regression

#### 6.4.6 Effects of Negative Salts

The effects of five different salts on mercury absorption in Hg(II) was investigated by sequentially injecting HgCl<sub>2</sub> and salts.

Figure 6.17 Hg absorption in water with sequential  $HgCl_2$  and  $MnSO_4$  injections at  $25^\circ C$ . The injected  $Hg(II)$  ranged from 17 to 42  $\mu M$  while  $Mn(II)$  ranged from 40 to 380 mM.

#### 6.4.6.1 The Effect of NaCl

The  $K_g'$  of mercury was smaller than that of  $HgCl_2$  alone when 0.1 M NaCl was present in the solution. This indicates that the addition of NaCl inhibited mercury absorption in  $Hg(II)$ . The comparison is illustrated in figure 6.22.

Table 6.10 summarizes the results of Hg absorption in  $Hg(II)$ -NaCl at  $25^\circ C$  with and without oxygen. In the experiment with 20% oxygen mixed with

elemental mercury vapor,  $8.8 \times 10^{-6}$  and  $5.5 \times 10^{-5}$  M  $\text{HgCl}_2$  were injected into 1 M NaCl solution in which pH was maintained at 6.77-6.78. No mercury removal was observed. Another  $3.54 \times 10^{-4}$  M  $\text{HgCl}_2$  injection caused the outlet Hg concentration to decrease immediately but gradually increase to near the inlet Hg concentration. pH ranged from 6.72 to 6.73 at this last injection. In an earlier experiment, no  $\text{O}_2$  was present in the gas phase and the NaCl concentration was 10 times lower (0.1 M NaCl). Measurable Hg removal was observed when  $\text{HgCl}_2$  was injected and the normalized Hg flux was lower than with pure water by two orders of magnitude (refer to figure 6.18). This indicates that NaCl inhibits Hg absorption in  $\text{Hg(II)}$  and the magnitude of the negative effect on Hg removal is proportional to the concentration of NaCl. NaCl inhibits Hg absorption in  $\text{Hg(II)}$  and the magnitude of the negative effect on Hg removal is proportional to the concentration of NaCl.

Table 6.10 The effect of oxygen and NaCl on Hg absorption in NaCl at 25°C.

NaCl (M)	$\text{O}_2$ (%)	$\text{HgCl}_2$ injected (M)	pH	Results or $K_g'$ ( $\frac{\text{mole}}{\text{s-m}^2\text{-atm}}$ )
1	20	$8.8 \times 10^{-6}$	6.78	0
1	20	$5.5 \times 10^{-5}$	6.77	0
1	20	$3.5 \times 10^{-4}$	6.72	$\text{Hg}_{\text{out}} < \text{Hg}_{\text{in}}^*$
0.1	0	$5.2 \times 10^{-6}$	-	$5.8 \times 10^{-4}$
0.1	0	$1.3 \times 10^{-4}$	-	$1.9 \times 10^{-2}$
0.1	0	$3.5 \times 10^{-4}$	-	$4.6 \times 10^{-2}$

\* The  $\text{HgCl}_2$  injection caused the outlet Hg concentration to decrease immediately but gradually increased to near the inlet Hg concentration. So the  $K_g'$  value was very small in this case.

#### 6.4.6.2 The Effect of $\text{MgSO}_4$

The presence of  $\text{MgSO}_4$  inhibited the Hg removal ability of  $\text{Hg}(\text{II})$ . The addition of  $9.8 \times 10^{-5} \text{ M}$   $\text{HgCl}_2$  to  $0.02 \text{ M}$   $\text{MgSO}_4$  gave less Hg removal than  $6.8 \times 10^{-5} \text{ M}$   $\text{HgCl}_2$  alone without  $\text{MgSO}_4$ . The results are given in figure 6.18.

Figure 6.18 The effect of  $\text{MgSO}_4$  on Hg absorption in  $\text{Hg}(\text{II})$  at  $25^\circ\text{C}$ . Total  $\text{Hg}-\text{N}_2$  flow rate was  $1 \text{ l/min}$ .

#### 6.4.6.3 The Effect of $\text{FeCl}_3$

$\text{FeCl}_3$  alone did not remove Hg. The presence of  $\text{FeCl}_3$  inhibited the Hg removal ability of  $\text{Hg}(\text{II})$ . The addition of  $1.6 \times 10^{-5} \text{ M}$   $\text{HgCl}_2$  to  $0.01 \text{ M}$   $\text{FeCl}_3$  had

the same Hg removal as  $7.7 \times 10^{-6}$  M  $\text{HgCl}_2$  alone without  $\text{FeCl}_3$ . The results are given in figure 6.19.

Figure 6.19 The effect of  $\text{FeCl}_3$  on Hg absorption in  $\text{Hg}(\text{II})$  at  $25^\circ\text{C}$ . Total  $\text{Hg-N}_2$  flow rate was 1 l/min.

#### 6.4.6.4 The Effect of $\text{CaCl}_2$

$\text{CaCl}_2$  alone did not remove Hg. The presence of  $\text{CaCl}_2$  inhibited the Hg removal ability of  $\text{Hg}(\text{II})$ . The addition of  $2.3 \times 10^{-4}$  M  $\text{HgCl}_2$  to 0.09 M  $\text{CaCl}_2$  had less Hg removal than  $6.8 \times 10^{-5}$  M  $\text{HgCl}_2$  without  $\text{CaCl}_2$ . The results are given in figure 6.20.

Figure 6.20 The effect of  $\text{CaCl}_2$  on Hg absorption in  $\text{Hg}(\text{II})$  at  $25^\circ\text{C}$ . Total  $\text{Hg}/\text{N}_2$  flow rate was 1 l/min.

#### 6.4.6.5 The Effect of $\text{MgCl}_2$

$\text{MgCl}_2$  alone did not remove Hg. The presence of  $\text{MgCl}_2$  inhibited the Hg removal ability of  $\text{Hg}(\text{II})$ . This was concluded from the fact that  $2.1 \times 10^{-5}$  M  $\text{HgCl}_2$  in 0.04 M  $\text{MgCl}_2$  had almost the same Hg removal capability as that of  $7.7 \times 10^{-6}$  M  $\text{HgCl}_2$  without  $\text{MgCl}_2$ . The results are given in figure 6.21.

Figure 6.21 The effect of  $MgCl_2$  on Hg absorption in  $Hg(II)$  at  $25^\circ C$ . Total  $Hg/N_2$  flow rate was 1 l/min.

Figure 6.22 summarizes the effects of the above discussed five different salts. The overall third-order rate constant,  $k_3'$ , assuming a second-order dependence on  $Hg(II)$ , was obtained from:

$$N_{Hg} = \frac{P_{Hgi}}{H_{Hg}} \sqrt{k_3' D_{Hg-H_2O} [Hg(II)]_i^2} \quad (6-29)$$

All of the above salts inhibited the Hg removal ability of  $Hg(II)$ .

Figure 6.22 The effect of salts (concentrations in M) on Hg absorption at 25°C.  $k_3'$  was obtained from equation (6-29). Filled squares represent data with 20%  $O_2$  while empty squares with  $N_2$  only. All other legends represent data with  $N_2$ .

#### 6.4.7 SUMMARY OF RESULTS

Table 6.11 gives the summary of rate constants obtained for different aqueous systems. The second and third order rate constants,  $k_2$  and  $k_3$ , are calculated from  $N_{Hg} = \frac{P_{Hgi}}{H_{Hg}} \sqrt{k_2 D_{Hg-H_2O} [Hg(II)]_i}$  (6-30)

or:

$$N_{Hg} = \frac{P_{Hgi}}{H_{Hg}} \sqrt{k_3 D_{Hg-H_2O} [Hg(II)]_i [\text{other active reagent}]_i} \quad (6-31)$$

respectively.

Table 6.11 Summary of the second and third order rate constants,  $k_2$  and  $k_3$ , for mercury absorption in different aqueous systems.

Aqueous Solution	T °C	$k_2 \times 10^{-6}$ $\frac{l}{M \cdot s}$	$k_3 \times 10^{-8}$ $\frac{l}{M^2 \cdot s}$
HgCl <sub>2</sub> -0.8 M HNO <sub>3</sub>	25	7.8 ± 2.1	-
	55	13.4 ± 8.0	
HgCl <sub>2</sub> -H <sub>2</sub> O <sub>2</sub> -0.8 M HNO <sub>3</sub>	25	-	4.0 ± 1.1
	55		88.8 ± 9.9
HgCl <sub>2</sub> -K <sub>2</sub> Cr <sub>2</sub> O <sub>7</sub> -0.8 M HNO <sub>3</sub>	25	14	4.3*
HgCl <sub>2</sub> -MnSO <sub>4</sub>	25	-	0.44

\* was measured at 32 mM K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub> and various HgCl<sub>2</sub> in 0.8 M HNO<sub>3</sub>

Although the aqueous systems studied were diversified, they all exhibited first order dependence on Hg(II). To compare different systems, the Hg(II) concentration must be specified along with other active liquid or gas components. The effectiveness of the system for Hg removal is expressed as normalized flux,  $K_g'$ . The results are listed in table 6.12. At 10<sup>-5</sup> M Hg(II), 0.26 M H<sub>2</sub>O<sub>2</sub>-0.8M HNO<sub>3</sub> gives the best mercury removal, followed by 0.03 M K<sub>2</sub>Cr<sub>2</sub>O<sub>7</sub>-0.8 M HNO<sub>3</sub>, and then 0.1 or 0.8 M HNO<sub>3</sub>, or 0.8 M H<sub>2</sub>SO<sub>4</sub>.

Table 6.12 Comparison of  $K_g'$  and  $k_2$  at three Hg(II) levels among different systems at 25°C. Data inside parentheses are extrapolated values rather than experimental data. "-" indicates that either no experimental data available or extrapolation was not possible.

Liquid & Gas Composition	Hg(II) M	$K_g' \times 10^6$ $\frac{\text{mole}}{\text{s-atm-cm}^2}$	$k_2 \times 10^{-6} *$ $\frac{1}{\text{M-s}}$	Solution pH

## **Chapter 7 Mercury Absorption in Aqueous Hypochlorite and Chlorine**

Elemental mercury absorption in sodium hypochlorite was investigated over a wide range of hypochlorite concentration and solution pH. Aqueous free chlorine was the active species that oxidized  $\text{Hg}^0$ . An apparent overall second order reaction was observed between  $\text{Hg}^0$  and aqueous free chlorine with  $k_2 = 1.7 \times 10^{15} \text{ M}^{-1}\text{s}^{-1}$  at  $25^\circ\text{C}$  and  $1.4 \times 10^{17} \text{ M}^{-1}\text{s}^{-1}$  at  $55^\circ\text{C}$ . Chlorine desorption was evident at high  $\text{Cl}^-$  when pH was less than 9. Because of  $\text{Cl}_2$  desorption at low to intermediate pH with high  $\text{Cl}^-$ , kinetic information was difficult to obtain in that region. However, data gathered at low to intermediate pH with low  $\text{Cl}^-$  agreed well with results of high pH with high  $\text{Cl}^-$ , when concentration was corrected for the effect of ionic strength.

Because of chlorine desorption at low to intermediate pH with high  $\text{Cl}^-$ , the reaction between gaseous chlorine and  $\text{Hg}^0$  vapor was further investigated. A fast reaction occurred between  $\text{Hg}^0$  and chlorine at room temperature on apparatus surfaces. Chlorine concentration, moisture, and solid surface area contributed positively to mercury removal.

### **7.1 PREVIOUS WORK**

#### **7.1.1 Mercury Oxidation by Hypochlorite**

The capability of hypochlorite to dissolve mercury has long been recognized. Parks and Baker (1969) described the recovery of mercury by contacting mercury containing material with a hypochlorite solution maintained at

pH of 4.5 to 9.5 to dissolve mercury in the hypochlorite solution. Nguyen (1979) demonstrated the use of hypochlorite to treat mercury-containing waste water from chlor-alkali plants. Nene and Rane (1981) reported quantitative results on mercury absorption in 5.8-27 mM sodium hypochlorite and 2.6-9.5 mM hypochlorous acid. They concluded that hypochlorous acid was much more reactive than hypochlorite. With hypochlorite, reactivity further increased in the presence of sodium or potassium chloride. Potassium hypochlorite was more reactive than sodium hypochlorite.

#### **7.1.2 Gas Phase Reaction of Mercury and Chlorine**

Medhekar et al. (1979) reported surface reaction of mercury with chlorine at 250°C to form a compound with a stoichiometric formula of  $(\text{HgCl}_2)_n$ . Cylindrical test cells made from four different materials were tested. Their initial observations rated the reactivity in the sequence: Teflon-coated stainless steel > stainless steel > quartz > Inconel. However, it was also observed that after several runs the reaction rate became faster until it eventually became independent of the surface material. They concluded that it was likely that the reaction products formed on the surface  $(\text{HgCl}_2)$  coated the surfaces and thus made all surfaces essentially the same.

Other investigators observed reaction between mercury and chlorine as well. McCannon and Woodfin (1977) reported that a reduced amount of mercury vapor was detected by atomic absorption if the gas mixture contained more than a few ppm chlorine. The reduction in mercury vapor concentration was attributed to the formation of reaction products between mercury and chlorine. Menke and

Wallis (1980) studied the gas phase reaction of mercury with chlorine in a cylindrical quartz tube with four levels of  $\text{Cl}_2$  concentration (0, 0.5, 1.5 and 3.8 ppm) and two levels of relative humidity (13% and 80%). They concluded that at constant mercury concentration, the rate of the formation of  $\text{Hg-Cl}_2$  reaction product (possibly  $\text{HgCl}_2$ ) increased with chlorine concentration and relative humidity. They also observed adsorption of  $\text{Hg-Cl}_2$  reaction product on the quartz walls.

## **7.2 EXPERIMENTAL METHOD**

All experiments were performed in the well-characterized stirred cell reactor with Teflon surfaces described in chapter 3.

In a typical experiment, 1.06 liters of distilled water was put into the reactor while  $\text{Hg}^0$  in nitrogen bypassed the reactor. After the mercury analyzer gave a stable reading, the mercury stream was passed over the distilled water inside the reactor. This condition was used to calibrate the analyzer. After the analyzer gave a stable reading, known amounts of sodium hypochlorite solution (Fisher Scientific, Purified Grade, 4-6 wt%) were sequentially injected into the water using a syringe with a long needle. In some experiments, a small amount ( $\leq 1$  ml) of 0.01 or 0.1 M HCl (EM Science, 36.5-38 wt%, GR) or NaOH (Spectrum Chemical, pellets) solution was injected to modify pH while  $\text{Hg-N}_2$  was passed over the solution. The outlet concentration of  $\text{Hg}^0$  was analyzed continuously and recorded by the strip chart recorder (Soltec Model 1242).

The rate of mercury absorption was calculated from the gas phase material balance. A three-point calibration was performed before and after each run to

account for the effect of base line drifting of the mercury analyzer. Hypochlorite addition to the liquid phase was determined by titration (Appendix F). When hypochlorite was too dilute to be titrated, the syringe was weighed before and after the injection to obtain the amount of hypochlorite injected.

During the studies of gas phase reaction of mercury and chlorine (Matheson Gas Products, 972 ppm Cl<sub>2</sub> with N<sub>2</sub> balance), a variety of apparatus configurations were used. The largest Teflon surface area was exposed with all of the tubing and the reactor in the gas flow path. When the gas stream bypassed the reactor, the surface area of the reactor was excluded. When the gas stream bypassed the reactor and all of the tubing before the analyzer, the least amount of surface area was exposed to the Hg-Cl<sub>2</sub> stream.

### 7.3 MASS TRANSFER WITH SIMULTANEOUS CHEMICAL REACTION

In aqueous hypochlorite solution, the distribution of OCl<sup>-</sup>, HOCl and Cl<sub>2</sub> depends on solution pH and [Cl<sup>-</sup>]. Since lower pH gives higher Hg removal, it is possible that free Cl<sub>2</sub> is the active species that reacts with Hg. Due to the wide concentration ranges of NaCl and NaOCl in the solution, the ionic strength has a significant impact on the interpretation of experimental results. The activities of the aqueous species were used instead of concentrations. The activity of free Cl<sub>2</sub> can be obtained from the two equilibria:

where:

$$K_1 = \frac{a_{\text{H}^+} a_{\text{OCl}^-}}{a_{\text{HOCl}}} \quad (7-3)$$

$$K_2 = \frac{a_{HOCl} a_{Cl^-} a_{H^+}}{a_{Cl_2}} \quad (7-4)$$

and:

$$[\text{Total NaOCl}] = [Cl_2] + [OCl^-] + [HOCl] \quad (7-5)$$

$$a_{H^+} = 10^{(-\text{measured pH})} \quad (7-6)$$

$$a_{HOCl} = \gamma_{HOCl} [HOCl] \quad (7-7)$$

$$a_{OCl^-} = \gamma_{OCl^-} [OCl^-] \quad (7-8)$$

$$a_{Cl_2} = \gamma_{Cl_2} [Cl_2] \quad (7-9)$$

$$a_{Cl^-} = \gamma_{Cl^-} [Cl^-] \quad (7-10)$$

$$a_{NaCl} = \gamma_{NaCl} [NaCl] \quad (7-11)$$

Thus:

$$a_{Cl_2} = \frac{[\text{Total NaOCl}]}{\frac{1}{\gamma_{Cl_2}} + \frac{K_2}{\gamma_{HOCl} a_{Cl^-} a_{H^+}} + \frac{K_1 K_2}{\gamma_{OCl^-} a_{Cl^-} a_{H^+}^2}} \quad (7-12)$$

By using the following assumptions,

$$\gamma_{Cl_2} = \gamma_{HOCl} = 1 \text{ (} \gamma \text{ of molecule is near 1)} \quad (7-13)$$

$$\gamma_{Cl^-} = \gamma_{OCl^-} = \gamma_{NaCl} \quad (7-14)$$

equation (7-12) can be simplified to:

$$a_{Cl_2} = \frac{[\text{Total NaOCl}]}{1 + \frac{K_2}{\gamma_{NaCl} [Cl^-] a_{H^+}} + \frac{K_1 K_2}{\gamma_{NaCl}^2 [Cl^-] a_{H^+}^2}} \quad (7-15)$$

$\gamma_{NaCl}$  is the mean activity coefficient of aqueous NaCl solution (  $\gamma_{NaCl} = \sqrt{\gamma_{Cl^-} \gamma_{Na^+}}$  ) and its value is determined using the effective NaCl concentration:

$$[NaCl]_{\text{effective}} = [NaCl] + [NaOCl] \quad (7-16)$$

$\gamma_{NaCl}$  is 0.996, 0.903, 0.779 and 0.657 for 0.001, 0.01, 0.1 and 1 M NaCl at 25°C, respectively.  $\gamma_{NaCl}$  is 0.768 for 0.1 M NaCl and 0.655 for 1 M NaCl at

55°C (Robinson and Harned, 1941; Lobo and Quaresma, 1989). The temperature dependence of equilibrium constants is given in table 7.1.

Table 7.1 Equilibrium constants at two different temperatures.

Equilibrium Constant	25°C	55°C
$K_1 (M)^*$	$3.00 \times 10^{-8}$	$4.46 \times 10^{-8}$
$K_2 (M^2)^\ddagger$	$3.94 \times 10^{-4}$	$7.10 \times 10^{-4}$

\*obtained from Atkins (1990)

‡Obtained from Connick and Chia (1959)

We have found that the rate of reaction between elemental mercury vapor and hypochlorite is given by the mechanism:

At constant pH the reaction rate is given with the second order rate constant,  $k_2$ :

$$\text{reaction rate} = k_2 [\text{Hg}] [\text{Cl}_2] \quad (7-18)$$

Using surface renewal theory with fast reaction near the gas-liquid interface, the flux of elemental mercury,  $N_{\text{Hg}}$ , should be given by:

$$N_{\text{Hg}} = \frac{P_{\text{Hgi}}}{H_{\text{Hg}}} \sqrt{k_2 D_{\text{Hg-H}_2\text{O}} [\text{Cl}_2]_i} \quad (7-19)$$

where:

$$P_{\text{Hgi}} = P_{\text{Hgb}} - \frac{N_{\text{Hg}}}{k_{\text{g.Hg}}} \quad (7-20)$$

$$[\text{Cl}_2]_i \approx [\text{Cl}_2]_b \quad (7-21)$$

#### 7.4 MERCURY ABSORPTION IN SODIUM HYPOCHLORITE

Figure 7.1 gives the results of  $\text{Hg}^0$  absorption in aqueous sodium hypochlorite. Although there is no indication of the presence of NaCl in NaOCl by the manufacturer, it is reasonable to assume that for every mole of NaOCl,

there is one mole of NaCl in NaOCl solution. This assumption is based on the fact that NaOCl was manufactured by bubbling chlorine through NaOH:

Injections of NaOCl resulted in step decreases in the outlet  $\text{Hg}^\circ$  concentration. This indicates that NaOCl (with NaCl) absorbs mercury readily even at high pH. All the systems that we have studied previously absorb Hg well only at low pH with the presence of strong acid and oxidizer. Hypochlorite is the only oxidizer we have tested that substantially removes mercury at high pH.

Figure 7.1 Hg absorption in NaOCl at 25°C. NaOCl concentration is obtained from the cumulative amount injected. pH ranged from 10.7 to 11.2. NaCl concentration is assumed to be the same as that of the cumulative amount of NaOCl. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

Figure 7.2 Hg absorption in NaOCl and HgCl<sub>2</sub> at 25°C. The concentrations of NaOCl and HgCl<sub>2</sub> are cumulative amounts from injection quantities. pH ranged from 10.2 to 11.1. NaCl concentration is assumed to be the same as that of cumulative amount of injected NaOCl. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

When a small concentration of HgCl<sub>2</sub> was injected into relatively large amount of NaOCl, the net effect of HgCl<sub>2</sub> was not apparent. However, when relatively large changes in HgCl<sub>2</sub>, such as 10<sup>-4</sup> M, were made in 0.1 M NaOCl, the net effect of HgCl<sub>2</sub> was significant, as shown in the step decreases in the outlet Hg concentration in figure 7.2. HgCl<sub>2</sub> itself did not help to absorb more Hg (refer to section 7.4.4), but rather it reduced the solution pH. Lower pH favors Hg absorption in NaOCl, as shown in section 7.4.2. Small HgCl<sub>2</sub> addition to large

amount of NaOCl did not lower solution pH significantly. On the contrary, large addition of  $\text{HgCl}_2$  to relatively dilute NaOCl lowers solution pH significantly and thus absorbs Hg more readily.

#### 7.4.1 Effect of NaCl

The effect of NaCl was investigated by injecting NaOCl into 0.1 and 1 M NaCl solution. The results are given in figure 7.3.

Figure 7.3 The effect of NaCl on Hg absorption in NaOCl at 25°C. Total Hg- $\text{N}_2$  flow rate was 1 l/min.

With a trace amount of NaOCl, the existence of 1 M NaCl greatly enhanced mercury absorption. At  $10^{-5}$  M NaOCl, the normalized flux was

increased by a factor of 70. Controlled pH experiments described later in this chapter indicate that lower pH favors mercury absorption. From the chlorine hydrolysis reaction:

It is obvious that lower pH and higher  $\text{Cl}^-$  produce more free  $\text{Cl}_2$  in the solution. Therefore it is probable that free chlorine is the active species reacting with mercury.

Because of the positive effect of NaCl on mercury absorption in NaOCl, two levels of high NaCl were tested. Figure 7.4 gives the results with 0.1 and 1 M NaCl at controlled pH. The low pH was obtained by adding HCl. At 0.1 M NaCl, injections of both  $9.2 \times 10^{-7}$  and  $2.9 \times 10^{-6}$  M NaOCl caused the outlet Hg to decrease immediately. However, the outlet Hg increased shortly after NaOCl was injected. The outlet mercury concentration continuously increased until it approached the inlet mercury concentration. With 1 M NaCl, injections of NaOCl in the same range caused the outlet mercury concentration to decrease and stabilize at the reduced value. The results indicate that the presence of NaCl either helped absorbed mercury stay in the solution, or it produced enough free chlorine to continuously absorb mercury, or the produced free chlorine desorbed and reacted with Hg on apparatus surfaces.

Figure 7.4 The effect of NaCl on Hg absorption in NaOCl at 25°C and pH 3. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

#### 7.4.2 Effect of pH

Figure 7.5 gives the effect of pH on mercury absorption in NaOCl with 1 M NaCl. Lower pH favors mercury absorption. This further indicates that aqueous free chlorine is the active ingredient reacting with Hg. At very high pH, such as pH 11, large amount of NaOCl needs to be injected to reach or near gas phase control. However, at pH 10 or lower, gas phase control was fairly easy to achieve. At intermediate pH, there were some  $K_g'$  that exceeded  $k_g$ . This extra

amount of Hg removal might have been caused by surface reaction of Hg with desorbed chlorine, which will be discussed in section 7.5.

Figure 7.5 The effect of pH during Hg absorption in 1 M NaCl with sequential injections of NaOCl at 25°C. No external HgCl<sub>2</sub> injections were made. Total Hg-N<sub>2</sub> flow rate was 1 l/min. Data points for pH < 9 represent the maximum fluxes associated with each injection of NaOCl.

Figure 7.6 gives the activity coefficient of NaCl for concentrations upto 1 M at 25°C.  $\gamma_{NaCl}$  is 0.768 for 0.1 M NaCl and 0.655 for 1 M NaCl at 55°C (Robinson and Harned, 1941).

Figure 7.6 The dependence of activity coefficient of NaCl on its concentration at 25°C (Lobo and Quaresma, 1989).

---

---

Figure 7.7 gives the dependence of normalized flux,  $K_g'$ , on the estimated activity of free aqueous  $\text{Cl}_2$  using equation (7-15).  $9 \times 10^{-7}$  to 1 M NaCl and a pH range of 4.9 to 11.1 were used in these experiments. By assuming a 1:1 ratio of NaOCl to NaCl, results without externally adding NaCl to NaOCl were fitted successfully with controlled NaCl-controlled pH results. The data are tabulated in tables 7.2a, 7.2b and 7.2c.

Figure 7.7 Hg absorption in NaOCl-NaCl at 25°C. The wide pH range was obtained by adding NaOCl, HgCl<sub>2</sub> or NaOH. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

Table 7.2a Mercury absorption in NaOCl with or without HgCl<sub>2</sub> injection at 25°C. The inlet Hg was 97.7 ppb.  $k_{g, \text{Hg}} = 0.39$  mole/s-atm-m<sup>2</sup> and  $k'_{l, \text{Hg}^{++}} = 2.2 \times 10^{-5}$  m/s. NaCl concentration was assumed to be the same as that of the cumulative amount of NaOCl. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

### 7.4.3 Effect of Temperature

Figure 7.8 gives the results of experiments conducted at 25 and 55°C.

For controlled pH and NaCl experiments with  $\text{pH} \geq 9$  and  $\text{Cl}^- \geq 0.1 \text{ M}$ , an overall second order reaction between Hg and  $\text{Cl}_2$  was observed. The combination of high pH and low  $\text{Cl}^-$  also gave good results. In addition, the same second order behavior was obtained with low  $\text{Cl}^-$  and low pH, such as with  $\text{pH} = 4.9$  and  $\text{Cl}^- = 8.5 \times 10^{-6} \text{ M}$ .

Figure 7.8 Hg absorption in NaOCl-NaCl at 25 and 55°C. Data at 25°C included some low to intermediate pH results with low  $\text{Cl}^-$ . No  $\text{HgCl}_2$  injection was made. Total Hg- $\text{N}_2$  flow rate was 1 l/min.

High temperature favors mercury absorption. At 25°C, all data points gave reasonably good fit to second order kinetics. However, high chlorine points at 55°C tended to give higher mercury flux, as shown in figure 7.8. The data of high pH at 55°C are given in table 7.2c. The free chlorine concentration was again calculated from equation (7-15).

The second order rate constant appears to be  $1.7 \times 10^{15} \text{ M}^{-1}\text{s}^{-1}$  at 25°C and  $1.4 \times 10^{17} \text{ M}^{-1}\text{s}^{-1}$  at 55°C.

#### **7.4.4 Effect of $\text{HgCl}_2$**

The effect of  $\text{HgCl}_2$  can be determined from table 7.2a. Since results obtained with external  $\text{HgCl}_2$  injections (ranged from  $4.8 \times 10^{-6}$  to  $1.0 \times 10^{-3} \text{ M}$ ) gave the same second order rate constant as those without external  $\text{HgCl}_2$  injection, it was concluded that the addition of  $\text{HgCl}_2$  did not affect Hg absorption in NaOCl-NaCl solution. The same conclusion can be reached from the results of low to intermediate pH with  $\text{Cl}^- \geq 0.1 \text{ M}$  (refer to figure 7.11). However, solution pH was lowered by the injection of  $\text{HgCl}_2$ . Lower pH resulted in more free aqueous chlorine and thus absorbed more Hg. It is only in this sense that  $\text{HgCl}_2$  helped to absorb more Hg.

#### **7.4.5 Results with $\text{pH} < 9$ and $\text{Cl}^- \geq 0.1 \text{ M}$**

At  $\text{pH} > 9$ , no  $\text{Cl}_2$  desorption was apparent. Results with pH as low as 4.9 and low  $\text{Cl}^-$  ( $8.5 \mu\text{M}$ ) also agreed well with those of  $\text{pH} > 9$  (no  $\text{Cl}_2$  desorption was experienced at low pH with low  $\text{Cl}^-$ ). This is expected since such a low amount of  $\text{Cl}^-$  ( $8.5 \mu\text{M}$ ) did not result in significant amount of  $\text{Cl}_2$ ). However, at  $\text{pH} < 9$  and  $\text{Cl}^- \geq 0.1 \text{ M}$ ,  $K_g'$  was lower than expected, as shown in figure 7.9.

During these experiments at low pH, the outlet mercury decreased immediately after NaOCl was injected and increased shortly after. Therefore, it is probable that severe chlorine stripping was occurring.

Figure 7.9 Hg absorption in NaOCl-NaCl at 25 and 55°C. Low and intermediate pH results are all with Cl<sup>-</sup> ≥ 0.1 M. High pH data at 25°C included some low to intermediate pH results with low Cl<sup>-</sup>. All data were those of without external HgCl<sub>2</sub> injection except some low to intermediate pH results with low Cl<sup>-</sup>. Data points for low and intermediate pH represent the maximum fluxes associated with each injection of NaOCl. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

At intermediate pH, Cl<sub>2</sub> desorption was experienced only at low NaOCl injections, such as 2.6x10<sup>-6</sup> M total NaOCl. After each injection of NaOCl, the

outlet Hg concentration decreased then increased to a steady-state value which was less than the inlet Hg concentration. With high NaOCl injection, solution pH was always higher than intermediate pH. So this was the same situation as that of  $\text{pH} > 9$  and no chlorine desorption was experienced. Due to the complicated chlorine desorption process, it is possible that the activity of free chlorine estimated by equation (7-15) did not represent actual free chlorine activity in the solution.

Figure 7.10 The effect of gas phase control on Hg absorption in NaOCl-NaCl at 25 and 55°C. Data points for low and intermediate pH represent the maximum fluxes associated with each injection of NaOCl. Total Hg-N<sub>2</sub> flow rate was 1 l/min.

At low and intermediate pH, NaOCl injection resulted in  $\text{Cl}_2$  desorption, with lower than expected Hg flux. High NaOCl injection gave results near or at gas phase control, as shown in figure 7.10. There are even several points that exceeded the gas phase control line. This may have been caused by additional reaction of mercury with chlorine in the gas phase catalyzed by the Teflon surface. Because of  $\text{Cl}_2$  desorption, the pH effects, and the high reactivity of  $\text{Cl}_2$  with Hg, both in the aqueous solution and gas phase, the kinetics was complicated at low to intermediate pH.

Figure 7.11 Effect of  $\text{HgCl}_2$  on Hg absorption in NaOCl-NaCl at 25°C. The low pH was obtained by adding HCl. 0.1 or 1 M NaCl was present. No external  $\text{HgCl}_2$  was injected except indicated in the legends otherwise. Data points represent the maximum fluxes associated with each injection of NaOCl. Total Hg- $\text{N}_2$  flow rate was 1 l/min.

External  $\text{HgCl}_2$  injections were made in low and intermediate pH experiments with  $\text{Cl}^- \geq 0.1 \text{ M}$ . The results are given in figure 7.11. It indicates one more time that  $\text{HgCl}_2$  did not affect Hg absorption in  $\text{NaOCl-NaCl}$ .

Results of the experiments at low and intermediate pH with high  $\text{Cl}^-$  are given in tables 7.3a, 7.3b, and 7.3c. Detailed results are listed in appendix G.

Table 7.3a Hg absorption in  $\text{NaOCl-NaCl}$  at low to intermediate pH at  $25^\circ\text{C}$ . Data represent the maximum flux in any single reagent addition. The inlet Hg was 97.7 ppb.  $k_{\text{g, Hg}} = 0.39 \text{ mole/s-atm-m}^2$  and  $k_{\text{l, Hg}^{++}}^\circ = 2.2 \times 10^{-5} \text{ m/s}$ . No external  $\text{HgCl}_2$  injection was made in all of the experiments.  $[\text{Hg}^{++}]_i = [\text{Hg}^{++}]_{\text{absorbed}} + \frac{N_{\text{Hg}}}{k_{\text{l, Hg}^{++}}^\circ}$ . \* with 1 M NaCl.

Appendix H gives the results when interfacial chlorine activity is used instead of bulk chlorine activity. Although this approach somewhat improves the results at low pH with high  $\text{Cl}^-$ , the  $K_g'$  is still lower compared to those of high pH results.

## **7.5 GAS PHASE REACTION OF ELEMENTAL MERCURY AND CHLORINE**

Due to chlorine desorption at  $\text{Cl}^- \geq 0.1 \text{ M}$  and  $\text{pH} < 9$ , kinetic information was difficult to obtain under these conditions. In order to understand this phenomenon, various amounts of chlorine were added to elemental Hg in the gas phase. It was estimated from previous experiments that the desorbed  $\text{Cl}_2$  during Hg absorption in NaOCl would not exceed 1 ppm. Thus it was assumed that adding a fixed amount of  $\text{Cl}_2$  greater than 1 ppm to the gas phase would minimize the effect of chlorine desorption.

Hg- $\text{Cl}_2$  was bypassed the reactor, absorbed into pure water and 1 M NaCl at different pH values. With the coexistence of chlorine and elemental mercury in the gas phase, less elemental mercury was detected at the outlet. Furthermore, higher chlorine concentration gave lower outlet elemental mercury concentration. This was experienced in every experiment. Thus it was concluded that more chlorine resulted in more reaction between elemental mercury and  $\text{Cl}_2$ .

At the same inlet  $\text{Cl}_2$  concentration, the degree of surface contact of the Hg- $\text{Cl}_2$  gas mixture affects results. It was shown that more solid surface area gave less elemental mercury in the outlet. When Hg- $\text{Cl}_2$  bypassed the reactor and Teflon tubes upstream of the analyzer and flowed directly to the mercury analyzer, the Hg- $\text{Cl}_2$  was only exposed to the surface of the gas blending tube and

of the analyzer. This is the first mode of operation in table 7.4. It gave the least amount of surface area exposure. Comparison of this mode to the second mode of normal bypassing shows that solid surface area, even with Teflon coated reactor surface and Teflon tubes, contributes to more reaction between elemental mercury and chlorine.

Table 7.4 Summarized results of chlorine reaction with elemental mercury at 25°C. The inlet Hg concentration was 97 ppb.

Mode	Mode Description	Estimated Teflon Surface Area (m <sup>2</sup> )	Inlet Cl <sub>2</sub> (ppm)	Outlet Hg (ppb)
1	Hg & Cl <sub>2</sub> bypassed the reactor and connected directly to Hg analyzer	0.0025	0 5 11 38	97 97 89 17
2	Hg & Cl <sub>2</sub> bypassed the reactor	0.019	0 5 30	97 14 1 - 5
3	only Hg absorbed in H <sub>2</sub> O Cl <sub>2</sub> added after the reactor	0.034	0 1.5 10	86 85 81
4	Hg & Cl <sub>2</sub> absorbed in H <sub>2</sub> O	0.034	0 1 10	87 71 9 - 14

The third mode in table 7.4 indicates that only Hg absorbed into water. Chlorine was added to the gas stream after the reactor. Under this mode of operation, chlorine was not exposed to a lot of moisture. Less Hg removal was expected.

The fourth mode in table 7.4 is Hg and chlorine absorbed in water. In this mode of operation, Hg was blended with chlorine before the reactor and absorbed into water with all the normal tubing system. In this mode, more mercury loss was observed. This indicates that moisture contributes positively to Hg reaction

with  $\text{Cl}_2$ . It is also expected that chlorine react with Hg quite readily at the water surface.

The history of the experiments also seems to influence the results. Table 7.5 gives the comprehensive experimental results. Each block in the table represents one experiment while each line inside the block represents one mode of operation. If a very high level of chlorine was introduced at the beginning of the experiment, it tended to give more reaction between mercury and chlorine even if a very small amount of chlorine was present later. This indicates that once the reactor or surface was coated with high levels of the reaction product of chlorine and mercury, more reaction could be expected.

Table 7.5 Summary of Hg removal when  $\text{Cl}_2$  was added to the gas phase. The experiments were conducted at  $25^\circ\text{C}$  with 15 l/min  $\text{N}_2$  dilution before the Hg analyzer. Hg- $\text{Cl}_2$ - $\text{N}_2$  or Hg- $\text{N}_2$  flow rate was 1 l/min and the inlet Hg was 97 ppb.

## **Chapter 8 Mercury Absorption in Simulated Limestone Slurry, Sulfide, and Polysulfide Solutions**

Many coal-fired power plants and municipal solid waste incinerators have been equipped with various flue gas desulfurization systems, mainly for the control of sulfur dioxide emissions. Mercury is removed in those systems. Field data showed a mercury collection efficiency of 25-50% for cold and 0% for hot electrostatic precipitators (Huang et al., 1991). A range of 50 to 90% mercury removal was indicated in a limited number of fabric filter systems (Smith, 1987; Chow, 1991). The most common system, limestone slurry scrubbing, appears to remove total mercury with an efficiency of 20-90% based on very few available results (Radian Corporation, 1989; Huang et al., 1991).

Vogg et al. (1986) studied mercury removal by wet scrubbing methods in laboratory scale experiments. They showed that mercuric chloride could be conveniently and very effectively eliminated from the gas phase through condensation. They also observed the possibility of mercury loss if divalent mercury was reduced, e.g. by sulfur dioxide. They then suggested that this could be counteracted by higher chloride concentrations, by a strongly acid scrubbing solution, or if possible, by lowering the temperatures or adding oxidants, such as ferric chloride.

The objective of this study was to test the effectiveness of limestone slurry scrubbing on mercury removal. Experimental results indicate that solutions with sulfite or thiosulfate did not absorb elemental mercury vapor, even with the presence of oxygen in the gas phase. Additives, such as ferrous sulfate and

succinic acid used in limestone slurry scrubbing, usually for sulfur dioxide removal, did not contribute to mercury removal either. Thus it is concluded that solutions typical of limestone slurry scrubbing did not remove elemental mercury under our experimental conditions.

Aqueous sodium sulfide and polysulfide were tested for mercury absorption as well. Neither of the above reagents remove gaseous elemental mercury effectively under our experimental conditions.

## **8.1 EXPERIMENTAL METHOD**

All experiments were performed in the well-characterized stirred cell reactor described in Chapter 3. Two modes of experimental operation were developed over the course of the research. The initial mode of operation is called Batch-with-Low-Gas-Flow-Rate. Batch means that all the liquid components were put into the reactor prior to mercury absorption. In this mode of operation, the initial unsteady-state stage was recorded along with the rest of the experiment, usually at steady-state. Because of the initial uncontrollable behavior with this batch mode of operation, it is difficult to interpret experimental data. Low-Gas-Flow-Rate means that the Hg/N<sub>2</sub> or Hg/air flow rate into the reactor was either 100 cc/min or 200 cc/min.

An improved experimental method was introduced later. It is named Injection-with-High-Gas-Flow-Rate. Injection means that with only background solution, such as water or nitric acid in the reactor, the active reagents were sequentially injected. This method is superior because of its reliability and reproducibility. In every experiment, a base line was recorded with Hg/N<sub>2</sub> or

Hg/air absorbed into the background solution where no mercury absorption was expected. All other data were then compared to the base line to determine the effects of injected reagents. High-Gas-Flow-Rate means that the Hg/N<sub>2</sub> or Hg/air flow rate into the reactor was 1000 cc/min. The High-Gas-Flow-Rate method gave reproducible and reasonable results for Hg absorption into distilled water. Because of the very limited solubility of elemental mercury in water, it is generally believed that water does not absorb elemental mercury. However, with low gas flow rate, there was always a certain amount of mercury loss in the reactor. This was probably due to the fact that mercury adsorbed on solid walls of the reactor system. With 1 l/min of gas flow rate, no visible mercury loss was observed when Hg was absorbed from Hg/N<sub>2</sub> into distilled water.

The following described in detail the procedures with the Injection-with-High-Gas-Flow-Rate method. In a typical experiment, 1.06 liters of distilled water or other background solution was put into the reactor while elemental mercury in nitrogen or air was bypassed the reactor. After the mercury analyzer gave a stable reading, the mercury stream was passed over the solution inside the reactor. This was the wet analyzer calibration. Again after the analyzer gave a stable reading, known amounts of the proposed reagent solution were sequentially injected into the reactor using a syringe with a long needle below the liquid surface. The outlet elemental mercury concentration was analyzed continuously and recorded by the strip chart recorder (Soltec Model 1242).

The rate of mercury absorption was calculated from the gas phase material balance. A four-point calibration was performed before and after each run to account for the effect of base line drifting of the mercury analyzer. Reagent

addition to the liquid phase was determined by weighing the syringe before and after the injection. The specifications of the reagents used are listed in table 8.1.

Table 8.1 Specifications of the chemicals used in the experiments.

## 8.2 SIMULATED LIMESTONE SLURRY SCRUBBING

Sulfite is the major component in limestone slurry. Solutions typical of limestone slurry scrubbing were tested for mercury removal. Although earlier results using Batch-with-Low-Gas-Flow-Rate indicated that elemental mercury was substantially absorbed in sulfite and/or thiosulfate solutions, later results using Injection-with-High-Gas-Flow-Rate indicated no significant mercury absorption. Because the reactor system is more likely to be a mercury sink at low gas flow rate than at high gas flow rate, and because of the difficulties and uncertainties in data interpretation associated with the batch mode of operation, we believe the results obtained using Injection-with-High-Gas-Flow-Rate. In addition, Injection-with-High-Gas-Flow-Rate was tested and confirmed in the permanganate system prior to the application of the method to limestone slurry scrubbing system. This further increased its credibility and reliability.

## 8.2.1 Sulfite and / or Thiosulfate

### 8.2.1.1 *Results with Injection-with-High-Gas-Flow-Rate Method*

The application of Injection-with-High-Gas-Flow-Rate provides an opportunity to examine the net effect of each of the solution components on mercury removal. A higher gas flow rate of 1 l/min was an integral part of the method. Figure 8.1 gives the results of two independent measurements with this method. With 19.7% O<sub>2</sub> in the gas phase, neither S(IV) injection into S<sub>2</sub>O<sub>3</sub><sup>=</sup>/succinic acid/Fe<sup>2+</sup> solution nor S<sub>2</sub>O<sub>3</sub><sup>=</sup> injection into succinic acid/Fe<sup>2+</sup> solution made a positive contribution to Hg removal. This suggests that neither sulfite nor thiosulfate are effective mercury removal reagents, even with oxygen. Although high mercury removal was achieved in both runs, it was probably the effects of the initial solution rather than S(IV) or S<sub>2</sub>O<sub>3</sub><sup>=</sup>. Reactor system contamination could be the possible cause for this high mercury removal.

Table 8.2 gives the results using Injection-with-High-Gas-Flow-Rate. Elemental mercury was mixed with nitrogen. Some experiments also included oxygen or NO<sub>2</sub> in the gas phase. Each block in the table represents one independent experiment. Each line represents one reagent injection, as described by the column of Reagents Injected. Each injected reagent concentration is the cumulative concentration, resulting from multiple injections of the same reagent. In the column of Hg Removal, each line represents the differential effect of each reagent injection. Little mercury removal was achieved for most of the experiments. There are three experiments with 40 to 75% mercury removal that might have been caused by reactor or flow path contamination.

Figure 8.1 Effects of S(IV) and  $S_2O_3^{=}$  injections on Hg absorption in 0.02M succinic acid and 0.02 mM  $Fe^{2+}$  with 19.7 %  $O_2$  in the gas phase at 55°C. Total gas flow was 1 l/min and the initial solution pH was 5.

In experiment 01-02-96 (table 8.2), 97 ppb Hg, 100 ppm  $NO_2$ , 15%  $O_2$ , and  $N_2$  were in the gas phase. 50 mM  $Na_2S_2O_3$ , 20 mM succinic acid and 0.02 mM  $FeSO_4$  were individually injected into the reactor. None of the injections caused visible mercury absorption. After that,  $1.76 \times 10^{-5}$  M  $HgCl_2$  was injected and a small amount of Hg removal was observed. Another  $2.90 \times 10^{-4}$  M  $HgCl_2$  injection resulted in more Hg removal. The final solution turned light grayish with very little, almost undetectable precipitant. The results are given in figure

8.2. Compared to the results with only  $\text{HgCl}_2$  injection and no other reagents, the presence of  $\text{Na}_2\text{S}_2\text{O}_3$ -succinic acid- $\text{FeSO}_4$  in the solution and  $\text{NO}_2$ - $\text{O}_2$  in the gas phase decreased the effect of  $\text{HgCl}_2$  on mercury absorption.

Figure 8.2 Comparison of  $\text{HgCl}_2$  effect on Hg removal in water at  $25^\circ\text{C}$  with  $\text{N}_2$  in the gas phase and in 50 mM  $\text{Na}_2\text{S}_2\text{O}_3$ -20 mM succinic acid-0.02 mM  $\text{FeSO}_4$  at  $55^\circ\text{C}$  with 100 ppm  $\text{NO}_2$ -15%  $\text{O}_2$  in the gas phase.

Table 8.2 Hg absorption in simulated limestone slurry solution using Injection-with-High-Gas-Flow-Rate method. The inlet elemental Hg concentration was 97 ppb, total gas flow rate was 1 l/min.

### 8.2.1.2 Results using Batch-with-Low-Gas-Flow-Rate

Prior to using Injection-with-High-Gas-Flow-Rate, earlier experiments were conducted with low gas flow rate (100 or 200 cc/min) and no reagent injection. Experiments using this method tended to give more mercury removal. The results are given in table 8.3 and figure 8.3.

Table 8.3 Hg absorption in simulated limestone slurry solution using Batch-with-Low-Gas-Flow-Rate.

\* 100 ppm NO<sub>2</sub> was present in the gas phase

\*\* 0.2 M CaCl<sub>2</sub> was present in the solution

Figure 8.3 Comparison of Hg absorption using two methods at 55°C. Both of the initial solutions contained 20 mM succinic acid and 0.02 mM  $Fe^{2+}$ .

Although some experimental results in table 8.3 gave as much as 93% mercury removal, others using Batch-with-Low-Gas-Flow-Rate gave very little mercury removal, as shown in figures 8.4 and 8.5. In these runs, although 15 to 25% mercury removal was observed, the actual mercury flux was small due to the low gas flow rate. These results show that without S(IV) in solution or  $O_2$  in the gas phase, Hg absorption is very limited and the calculated pseudo first order rate

constant  $k_1$ , where  $k_1 = \frac{(\frac{N_{Hg}}{P_{Hgi}}) \frac{H_{Hg}}{D_{Hg-H_2O}}}{2}$ , is close to zero. When both S(IV) and  $O_2$  were present, Hg removal was enhanced and  $k_1$  increased to  $1.0 \text{ sec}^{-1}$ , although it was still negligible. The results also show that 100 ppm  $NO_2$  in the gas phase has no apparent effect on Hg removal.

Figure 8.4 Mercury absorption in S(IV) or water at 25°C using Batch-with-Low-Gas-Flow-Rate. All S(IV) solution contained 20 mM succinic acid and 0.02 mM  $FeSO_4$ . Total Hg- $N_2$ , Hg-air or Hg-air- $NO_2$  flow rate was 200 cc/min.

The results at typical limestone slurry scrubber temperature, 55°C, are given in figure 8.5. When 15% O<sub>2</sub> was present in the gas phase, water alone and solution containing S(IV) gave the same amount of Hg removal and the removal was independent of S(IV) concentration. When 200 mM CaCl<sub>2</sub> was added to the solution at pH 2, Hg removal was inhibited and the calculated  $k_1$  was practically zero. With no CaCl<sub>2</sub>,  $k_1$  was approximately 1.0 sec<sup>-1</sup> and was negligible.

Figure 8.5 Effect of S(IV) on Hg removal in the presence of 15% O<sub>2</sub> at 55°C using Batch-with-Low-Gas-Flow-Rate. All S(IV) solution contained 0.02 M succinic acid and 0.02 mM FeSO<sub>4</sub>. Total Hg-air flow rate was 100 cc/min.

Figure 8.6 gives the results of Hg absorption in a variety of other solutions using the Batch-with-Low-Gas-Flow-Rate. Polysulfide solution was prepared by reacting sublimed sulfur with NaOH at 80°C. 40% mercury removal was achieved when total flow into the reactor was 200 cc/min. 0.01 M  $\text{Na}_2\text{S}_2\text{O}_3$  and 0.2 M NaOH alone gave only 10% and 5% Hg removal, respectively. At low gas flow rate, 5 to 10% removal is practically no removal. When 0.02 M succinic acid was added to 0.02 M  $\text{Na}_2\text{S}_2\text{O}_3$  at pH 5, it gave 85% Hg removal without  $\text{O}_2$  and 30% Hg removal when 15%  $\text{O}_2$  was added to the gas mixture.

Figure 8.6 Results with Batch-with-Low-Gas-Flow-Rate method at 25°C. Gas flow rate was 200 cc/min.

## 8.2.2 Effects of Additives

Typical additives in limestone slurry scrubbing were tested for mercury removal. The addition of  $\text{MnSO}_4$ ,  $\text{MgSO}_4$  or  $\text{MgCl}_2$  to sulfite or thiosulfate using Injection-with-High-Gas-Flow-Rate did not remove elemental mercury. Earlier results indicated that the addition of  $\text{CaCl}_2$  to sulfite (using Batch-with-low-Gas-Flow-Rate) inhibited mercury absorption.

### 8.2.2.1 *Results using the Injection-with-High-Gas-Flow-Rate*

Table 8.4 gives the results of the addition of  $\text{MnSO}_4$ ,  $\text{MgSO}_4$  or  $\text{MgCl}_2$  to sulfite or thiosulfate. Each block in the table represents one independent experiment. Each line represents one reagent injection, as indicated by the column called Reagents Injected. Each line in the column of Injected Concentration represents cumulative concentration, if it was resulted from multiple injections of the same reagent. In the column of Hg Removal, each line represents the differential effect of the reagent injection defined on the same line. For example, in the experiment with run ID of 02-22-96, 60 mM  $\text{MnSO}_4$  was injected followed by 18 mM  $\text{Na}_2\text{SO}_3$  injection. Then an additional  $\text{MnSO}_4$  injection of 40 mM was conducted. This gives a cumulative  $\text{MnSO}_4$  concentration of 100 mM. Another  $\text{MnSO}_4$  injection of 100 mM resulted in a cumulative  $\text{MnSO}_4$  concentration of 200 mM. All these injections gave no mercury removal.

In summary, results show that no mercury removal was detected with  $\text{MgSO}_4$  or  $\text{MnSO}_4$  injected into sulfite.

Experiments with  $\text{MgCl}_2$  injection are also tabulated in table 8.3. Two representative runs, 02-12-96 and 02-06-96, gave no mercury removal. The experiment on 02-12-96 was repeated the next day. Similar results were obtained.

Table 8.4 Effects of additives on Hg absorption in sulfite and thiosulfate at 25°C using Injection-with-High-Gas-Flow-Rate. Total Hg- $\text{N}_2$  flow rate was 1 l/min,  $\text{Hg}_{\text{in}}$  was 97 ppb.

\* with 20%  $\text{O}_2$  in the gas phase

<sup>∇</sup> white flaky precipitant formed immediately after  $\text{NaOH}$  was injected, but disappeared quickly

<sup>#</sup> the net effect of the individual injection actually increased the outlet Hg concentration

<sup>^</sup> this injection just brought the outlet Hg concentration back down to the same as the inlet, so overall there was no Hg removal up to this injection

On 02-07-96, adding sulfuric acid or sodium hydroxide to adjust the pH of  $\text{MgCl}_2$  - S(IV) solution resulted in dramatic Hg removal. In order to reproduce these results, another independent but similar experiment was conducted. Two  $\text{MgCl}_2$  injections followed by one sulfite injection were performed. Then either sulfuric acid or NaOH was injected. No dramatic Hg removal like that of 02-07-96 was observed. Although the concentrations of  $\text{MgCl}_2$  and sulfite injected in this experiment were different from those of 02-07-96, and pH values were not exactly the same in these two runs, the basic constituents and principles are the same. The lack of reproducibility suggests that the results of 02-07-96 is unreliable.

One explanation of the dramatic mercury removal observed on 02-07-96 could be that the injections of NaOH formed flaky precipitants. Mercury may have adsorbed on the surface of the precipitants.

#### **8.2.2.2      *Results using Batch-with-Low-Gas-Flow-Rate***

An earlier run using Batch-with-Low-Gas-Flow-Rate tested the effect of 0.2 M  $\text{CaCl}_2$  and the results are shown in table 8.2. Mercury removal was inhibited and the calculated pseudo first order rate constant  $k_1$ , was practically zero. With no  $\text{CaCl}_2$ ,  $k_1$  was approximately  $1.0 \text{ sec}^{-1}$ .

#### **8.2.3    Succinic Acid or Succinic Acid/Sodium Hydroxide Mixture**

Figure 8.7 gives the results of a screening experiment which was designed to test the net effect of succinic acid on mercury removal. With 19.7% oxygen and a total gas flow rate of 1 l/min, 13% Hg removal was obtained when there was only water in the reactor. This amount of mercury removal might have been

the result of reactor contamination, as was mentioned earlier. 0.02 mM  $\text{FeSO}_4$  was injected into the reactor and no additional Hg removal was observed. After this, the addition of 20 mM succinic acid resulted in dramatic mercury removal. Subsequent 1.4 mM  $\text{S}_2\text{O}_3^{=}$  and 67 mM  $\text{S}_2\text{O}_3^{=}$  made no big difference and the solution turned turbid due to the mixing of succinic acid and  $\text{NaS}_2\text{O}_3$  at low pH.

Figure 8.7 Effects of  $\text{Fe}^{2+}$ , succinic acid and  $\text{S}_2\text{O}_3^{=}$  injections on Hg absorption in  $\text{H}_2\text{O}$  with 19.7 %  $\text{O}_2$  in the gas phase at 55°C. Total Hg/air flow rate was 1 l/min. Solution pH was not adjusted (natural pH).

At this point, it seemed that succinic acid played an important role in Hg removal. Additional experiments were performed by injecting succinic acid alone

Table 8.5 Hg absorption in succinic acid-NaOH at 55°C using Injection-with-High-Gas-Flow-Rate method. The inlet Hg was 99 ppb, total flow rate was 1 l/min, 19.7% O<sub>2</sub> was present in the gas phase.

and mixtures of succinic acid and NaOH. These combinations give different solutions with pH from 2 to 12. They were tested for mercury absorption at 55°C with 19.7% oxygen in the gas phase. The results are given in table 8.5. Each block in the table represents one independent run with subsequent succinic acid or succinic acid/NaOH injections. The initial three experiments seemed to remove

mercury and gave a pseudo first order rate constant of 28 to 11390. However, three subsequent experiments with similar solution conditions did not removal mercury. The discrepancies might have been caused by reactor contamination which removed Hg in the initial three experiments. We tend to believe that succinic acid alone or the mixture of succinic acid and sodium hydroxide does not absorb mercury.

### 8.3 SODIUM SULFIDE AND POLYSULFIDE

Although earlier results using Batch-with-Low-Gas-Flow-Rate indicated a substantial amount of mercury absorption in sulfide or polysulfide, more reliable results obtained using Injection-with-High-Gas-Flow-Rate gave no mercury removal. Thus it was concluded that sodium sulfide or polysulfide did not remove elemental mercury under our experimental conditions.

#### 8.3.1 Results using Injection-with-High-Gas-Flow-Rate

The results of mercury absorption in sodium sulfide or polysulfide using Injection-with-High-Gas-Flow-Rate are given in table 8.6. Each block in the table represents one experiment while each line inside the block represents one injection of reagent. Most of the results gave no mercury removal when Hg was absorbed in sodium sulfide solution with or without oxygen in the gas phase. However, when the full scale of the strip chart recorder was reduced from 1 V or 500 mV to 200 mV, a small amount of mercury removal was observed, as indicated by the run with an asterisk in table 8.6. The second order rate constant  $k_2$  ranged from 66 to 306  $M^{-1}s^{-1}$ , where  $k_2$  was calculated from:

$$N_{Hg} = \frac{P_{Hgi}}{H_{Hg}} \sqrt{k_2 [Na_2S]_b D_{Hg-H_2O}} \quad (8-1)$$

The value of  $k_2$  is much smaller than that of Hg absorption in  $\text{HgCl}_2$  or  $\text{KMnO}_4$ . The oscillation of  $k_2$  resulted from the fluctuation in the outlet Hg concentration. The small amount of mercury removal observed might have been the effect of the improved sensitivity of the strip chart recorder.

Table 8.6 Hg absorption in sodium sulfide and polysulfide using Injection-with-High-Gas-Flow-Rate. Total Hg-air or Hg- $\text{N}_2$  flow rate was 1 l/min,  $\text{Hg}_{\text{in}}$  was 97 ppb.

Run ID	Temp. (C°)	Gas Phase $\text{O}_2$ Concentration (%)	Reagent Injected	Injected Reagent Concentration (mM)	Hg Removal
01-11-96	25	0	$\text{Na}_2\text{S}$	2.6	none
			$\text{Na}_2\text{S}$	8.3	none
			$\text{Na}_2\text{S}$	52	none
01-20-96	25	0	$\text{Na}_2\text{S}$	25	<3%
			$\text{Na}_2\text{S}$	71	
			$\text{Na}_2\text{S}$	111	
01-12-96	25	20	$\text{Na}_2\text{S}$	23.6	none
01-12-96	55	20	$\text{Na}_2\text{S}$	59.4	none
			$\text{Na}_2\text{S}$	112	none
01-25-96*	55	20	$\text{Na}_2\text{S}$	26	$k_2$ varied from 66 to 306 $\text{M}^{-1}\text{s}^{-1}$
			$\text{Na}_2\text{S}$	63	
			$\text{Na}_2\text{S}$	115	
01-22-96	25	0	polysulfide	55.6g/40 ml	none
			$\text{HgCl}_2$	0.21	none

Polysulfide solution was obtained by heating the mixture of sublimed sulfur solid and NaOH solution around 70-80°C. As shown in table 8.5, polysulfide did not remove mercury, even with the presence of mercuric chloride.

### 8.3.2 Results using Batch-with-Low-Gas-Flow-Rate

As discussed earlier, experiments conducted with low gas flow rate (100 and 200 cc/min) and no reagent injection gave orders of magnitude more mercury removal than those with the new injection method and high gas flow rate. This

was experienced again when Hg was absorbed in sodium sulfide and polysulfide. In figure 8.8, 93% Hg removal was achieved when total gas flow rate was 100 cc/min and sodium sulfide was put into the reactor before Hg was fed into the reactor.

Figure 8.8 Hg absorption in 100 mM Na<sub>2</sub>S at 55°C using Batch-with-Low-Gas-Flow-Rate. 15% O<sub>2</sub> was present in the gas phase. Total Hg-air flow rate was 100 cc/min. Initial solution pH was 12.86, run ID: 06-02-95.

---

Using Batch-with-Low-Gas-Flow-Rate, 40% mercury was absorbed by polysulfide solution. The results are summarized in table 8.7.

Table 8.7 Hg absorption in sodium sulfide and polysulfide using Batch-with-Low-Gas-Flow-Rate method.

Run ID	T (C°)	Gas Flow Rate (cc/min)	O <sub>2</sub> (%)	Hg <sub>in</sub> (ppm)	Reagent in the Batch	Reagent Conc. (mM)	pH	Hg Removal (%)
06-02-95	55	100	15	0.2	Na <sub>2</sub> S	100	12.86	93
04-21-95	25	200	0	0.1	polysulfide	‡	-	40

‡ The batch of polysulfide was obtained by mixing 0.1 M sublimed sulfur and 0.3 M NaOH at 80°C

## Chapter 9 Conclusions and Recommendations

### 9.1 CONCLUSIONS

#### 9.1.1 Strong Oxidants

Aqueous solutions with oxidation capability were effective for Hg absorption. It oxidized the sparingly soluble  $\text{Hg}^\circ$  to a more soluble form,  $\text{Hg(II)}$ , and stabilized it in the solution. Permanganate with sulfuric acid absorbed  $\text{Hg}^\circ$  effectively even at concentration as low as  $10^{-6}$  M.

$\text{NaOCl}$  strongly absorbs Hg even at high pH. Low pH, high  $\text{Cl}^-$  and high temperature favor mercury absorption. Aqueous free  $\text{Cl}_2$  was the active species that reacted with mercury. However, chlorine desorption was evident at high  $\text{Cl}^-$  and  $\text{pH} < 9$ .

Gas phase reaction was observed between Hg and  $\text{Cl}_2$  on apparatus surfaces at room temperature. Strong mercury absorption in water was also detected with  $\text{Cl}_2$  gas present. Chlorine concentration, moisture and surface area contribute positively to mercury removal.

#### 9.1.2 $\text{Hg(II)}$ without Oxidants

$\text{Hg(II)}$  catalyzed  $\text{Hg}^\circ$  absorption in aqueous solutions.  $\text{Hg(II)}$  alone removes  $\text{Hg}^\circ$  effectively. The addition of a strong acid to  $\text{Hg(II)}$ , such as  $\text{HNO}_3$  or  $\text{H}_2\text{SO}_4$ , greatly enhanced  $\text{Hg}^\circ$  absorption. However, the addition of  $\text{HCl}$  inhibited  $\text{Hg}^\circ$  absorption in  $\text{Hg(II)}$ .

Succinic acid- $\text{NaOH}$  buffer solution greatly enhanced  $\text{Hg}^\circ$  absorption in  $\text{Hg(II)}$  but  $\text{NaHCO}_3$ - $\text{NaOH}$  inhibited Hg absorption. Under most conditions,

oxygen in the gas phase did not have any effect on  $\text{Hg}^\circ$  absorption in  $\text{Hg(II)}$ . However, oxygen had a positive effect on Hg absorption in  $\text{Hg(II)}$  when  $\text{HCl}$  or  $\text{NaHCO}_3\text{-NaOH}$  was present in the solution.

The addition of  $\text{MnSO}_4$  to  $\text{Hg(II)}$  only slightly enhanced Hg absorption. On the other hand,  $\text{NaCl}$ ,  $\text{MgSO}_4$ ,  $\text{FeCl}_3$ ,  $\text{CaCl}_2$  and  $\text{MgCl}_2$  all inhibited Hg absorption in  $\text{Hg(II)}$ .

#### **9.1.3 Hg(II) with Oxidants**

When an oxidant was added to  $\text{Hg(II)}$ ,  $\text{Hg}^\circ$  absorption was further enhanced. The addition of  $\text{H}_2\text{O}_2$  to  $\text{HNO}_3$  gave the most  $\text{Hg}^\circ$  removal. The addition of  $\text{Fe}^{2+}$  or  $\text{Fe}^{3+}$  to  $\text{Hg(II)-H}_2\text{O}_2\text{-HNO}_3$  has no immediate effect.

Both  $\text{K}_2\text{Cr}_2\text{O}_7$  and  $\text{K}_2\text{Cr}_2\text{O}_7\text{-HNO}_3$  enhanced  $\text{Hg}^\circ$  absorption in  $\text{Hg(II)}$  and the positive effect of adding  $\text{HNO}_3$  was more apparent than that of adding  $\text{K}_2\text{Cr}_2\text{O}_7$ .

At  $10^{-5}$  M  $\text{Hg(II)}$ , 0.26 M  $\text{H}_2\text{O}_2\text{-0.8M HNO}_3$  gave the most mercury removal, followed by 0.03 M  $\text{K}_2\text{Cr}_2\text{O}_7\text{-0.8 M HNO}_3$ , and then 0.1 or 0.8 M  $\text{HNO}_3$ , or 0.8 M  $\text{H}_2\text{SO}_4$ .

#### **9.1.4 Limestone Slurry Scrubbing, $\text{Na}_2\text{S}$ and Polysulfide Solutions**

Solutions typical of limestone slurry did not remove  $\text{Hg}^\circ$  under our experimental conditions. Sodium sulfite and sodium thiosulfate were the main species tested in this research. Other typical limestone slurry additives, such as succinic acid,  $\text{FeSO}_4$ ,  $\text{CaCl}_2$ ,  $\text{MnSO}_4$ ,  $\text{MgSO}_4$ , and  $\text{MgCl}_2$ , did not make any difference when sulfite and/or thiosulfate were present in the solution.

Aqueous sodium sulfide and aqueous polysulfide were not effective for  $\text{Hg}^0$  absorption under our experimental conditions.

The Teflon-coated stirred tank reactor was appropriate and reliable for  $\text{Hg}^0$  absorption. Earlier runs using the stainless steel reactor gave results that were difficult to interpret because of the interactions between mercury and stainless steel.

## **9.2 RECOMMENDATIONS FOR FURTHER WORK**

1. Further study mercury absorption in hypochlorite over a wide range of pH by varying the inlet  $\text{Hg}^0$  concentration and liquid phase agitation speed. Varying inlet  $\text{Hg}^0$  will determine the order of reaction on  $\text{Hg}^0$ . If the limiting step is reaction rather than diffusion, varying the liquid phase agitation would not make any difference. However, liquid phase agitation would definitely have significant impact if the limiting step is diffusion rather than reaction.

2. Explore the possible  $\text{Hg}^0$  removal capabilities of other chlorine related strong oxidizers, such as  $\text{NaClO}_3$ ,  $\text{NaClO}_4$ ,  $\text{HClO}_3$ ,  $\text{HClO}_4$ , etc.

3. Investigate surface catalyzed mercury reaction with chlorine. Teflon, glass and stainless steel are some of the surface materials that can be used. Identify the reaction product and study the effect of solid mercuric chloride. If the surface is coated with  $\text{HgCl}_2$ , it might give different results compared to the situation when the surface is clean.

4. Investigate possible solid adsorbents for Hg and  $\text{HgCl}_2$ .  $\text{Na}_2\text{S}$  impregnated activated carbon, polysulfide, calcium based adsorbents and fly ash are some of the adsorbents that might be effective.

5. Add mercuric chloride to elemental mercury vapor stream. Study the simultaneous absorption of mercury and mercuric chloride. It has been shown that aqueous  $\text{HgCl}_2$  removes  $\text{Hg}^\circ$  vapor. It is possible that gaseous  $\text{HgCl}_2$  reacts with  $\text{Hg}^\circ$ . Furthermore,  $\text{HgCl}_2$  absorbs fairly easily in water and stays mainly in its molecular form as  $\text{HgCl}_2$  in the solution. This solution removes  $\text{Hg}^\circ$ .

6. Study the effect of sulfur dioxide and/or  $\text{NO}_x$  on mercuric chloride absorption, or simultaneous mercury and mercuric chloride absorption. Since  $\text{SO}_2$  is a reducing agent, it might reduce the absorbed  $\text{Hg(II)}$  back to  $\text{Hg}^\circ$  and desorb from the solution. On the other hand,  $\text{SO}_2$  absorbs in the solution itself and might form complexes with  $\text{Hg(II)}$ , which could render a completely different picture.

## **Appendix A Safety Procedures in Handling Mercury**

Due to the well-known health effects of mercury and its acute toxicity, special precautions must be followed when handling mercury. The American Conference of Governmental Industrial Hygienists has adopted the threshold limit value (TLV) of  $0.1 \text{ mg/m}^3$  (0.01 ppm) for mercury vapor and inorganic compounds of mercury for an eight hour work day. Since mercury can either be absorbed through the skin or inhaled, special protection procedures must be adopted.

### **A.1 FIRST AID**

Eye Contact: Flush with running water for 15 min., including under the eyelids.

Skin Contact: Remove contaminated clothing. Wash affected area with soap and water.

Inhalation: Remove to fresh air. Restore and/or support breathing as needed. Administer  $\text{O}_2$  for chemical pneumonitis.

Ingestion: Gastric lavage with 5% solution of sodium formaldehyde sulfoxylate, followed by 2%  $\text{NaHCO}_3$ , and finally leave 250 cc of the sodium formaldehyde sulfoxylate in the stomach.

### **A.2 PERSONAL PROTECTION**

Provide adequate exhaust ventilation to meet TLV requirements in the workplace. This was done by placing all mercury containing components of the apparatus inside the ventilation hood. When it was not being used, the mercury

source was sealed inside the U-tube without contacting the ambient air. According to the mercury Material Safety Data Sheets (MSDS), self-contained breathing apparatus can be used up to 5 mg/m<sup>3</sup> (0.5 ppm) with a full facepiece above 1 mg/m<sup>3</sup> (0.1 ppm). Since the highest inlet mercury concentration used in all experiments was 0.1 ppm, we used a half-face respirator (Cole-Parmer Instrument Company) whenever experimental personnel were near or partially inside the hood. Chemical safety glasses, rubber gloves and protective clothing appropriate for the work situation should be used to avoid body contact with mercury. Provide replacement and periodic medical exams for those regularly exposed to mercury, such as testing the blood sample for mercury concentration in a clinic. No eating or smoking in work areas.

### **A.3 SPILL, LEAK AND DISPOSAL PROCEDURES**

Notify safety personnel of leaks or spills. Provide adequate ventilation. Clean-up spills promptly. A suction bottle with a capillary tube for small amounts can be used. Vacuum cleaners may be used provided they have special mercury absorbent exhaust filters. Calcium polysulfide with excess sulfur can be sprinkled into cracks or other inaccessible places to convert mercury globules into the sulfide. Collect picked-up or scrapped mercury in tightly sealed containers for reclaim or for disposal. Do not discharge mercury down the drain. As for disposal procedure, mercury should be salvaged for purification or sold to a salvage company when large amounts are involved.

## Appendix B $D_{\text{Hg-H}_2\text{O}}$ Estimation

The diffusion coefficient of elemental mercury in water,  $D_{\text{Hg-H}_2\text{O}}$ , was estimated by the equation of Sitaraman et al. (1963):

$$D_{\text{Hg-H}_2\text{O}} = 16.79 \times 10^{-14} \left( \frac{M_{\text{H}_2\text{O}}^{0.5} \Delta H_{\text{H}_2\text{O}}^{1/3} T}{\mu_{10\% \text{ H}_2\text{SO}_4} V_{\text{Hg}}^{0.5} \Delta H_{\text{Hg}}^{0.3}} \right)^{0.93} \quad (\text{B-1})$$

where  $\Delta H_{\text{Hg}}$  and  $\Delta H_{\text{H}_2\text{O}}$  are the latent heats of vaporization of the solute and solvent at their normal boiling points:

$$\Delta H_{\text{Hg}} = 2.94776 \times 10^5 \text{ J/kg} \quad (\text{B-2})$$

$$\Delta H_{\text{H}_2\text{O}} = 2.257 \times 10^6 \text{ J/kg} \quad (\text{B-3})$$

and  $\mu_{10\%, \text{H}_2\text{SO}_4}$  is the viscosity of the reducing solvent in centipoise:

$$\mu_{10\%, \text{H}_2\text{SO}_4} = 1.256 \text{ cp (25}^\circ\text{C)} \quad (\text{B-4})$$

$V_{\text{Hg}}$  is the molar volume of solute at the normal boiling point:

$$V_{\text{Hg}} = 19 \times 10^{-3} \text{ m}^3/\text{kgatom} \quad (\text{B-5})$$

and  $M_{\text{H}_2\text{O}}$  is the molecular weight of solvent in kg/kgmol.

The predicted  $D_{\text{Hg-H}_2\text{O}}$  value is  $1.19 \times 10^{-5} \text{ cm}^2/\text{sec}$  at  $25^\circ\text{C}$  and  $2.21 \times 10^{-5} \text{ cm}^2/\text{sec}$  at  $55^\circ\text{C}$ .

## Appendix C Results of Hg Absorption in $\text{KMnO}_4$ -1.8 M $\text{H}_2\text{SO}_4$

## Appendix D Determination of H<sub>2</sub>O<sub>2</sub> by Iodometric Titration

Aqueous hydrogen peroxide concentration was determined by iodometric titration. An excess amount of potassium iodide was oxidized by hydrogen peroxide. The produced iodine was then back-titrated with thiosulfate to determine the amount of iodine produced. From the reaction stoichiometry, the hydrogen peroxide concentration can be determined.

The chemistry involved can be described as follows:

The procedures are described below:

1. Put 10 ml 0.3 M KI in 50 ml Erlenmeyer flask.
2. Add 2 ml of 1:1 (by volume) H<sub>2</sub>SO<sub>4</sub> to the flask
3. Add 3 drops of 1 N ammonium molybdate (reaction catalyst)
4. Extract 1 ml H<sub>2</sub>O<sub>2</sub> sample from the reactor and add the sample to the flask while constantly shaking the flask
5. Let solution stand for 5-10 min.
6. Titrate liberated I<sub>2</sub> with certified 1 N thiosulfate. Add thiosulfate until the solution turns from dark orange to pale yellow while shaking the solution. Slow down the addition of thiosulfate by adding the solution drop by drop until the solution is clear.

## Appendix F Determination of NaOCl by Iodometric Titration (Lagowski, 1995)

An oxidation-reduction (redox) titration was used to analyze the concentration of hypochlorite ion when high concentration of NaOCl was used. The iodide ion from the KI added to the solution is oxidized to iodine by the hypochlorite ion.

In the presence of free  $\text{I}^-$ , any  $\text{I}_2$  produced will combine with  $\text{I}^-$  to form  $\text{I}_3^-$ :

$\text{I}_3^-$  is called the triiodide ion. Stoichiometrically,  $\text{I}_3^-$  will react in the same ratio as the  $\text{I}_2$  molecule. Therefore, to simplify discussion,  $\text{I}_2$  molecule is used in all subsequent discussions even though  $\text{I}_3^-$  ion may actually be present in the solution.

The iodine produced in reaction (F-1) is titrated with standardized sodium thiosulfate. 0.5 M  $\text{H}_2\text{SO}_4$  is added at this point to provide an acidic reaction solution.

The thiosulfate titration is continued slowly until the yellow color disappears.

Procedure:

1. Add 1g of solid KI and 5 ml of 0.5 M  $\text{H}_2\text{SO}_4$  to 100 ml Erlenmeyer flask

2. Weigh the above solution and the Erlenmeyer flask
3. Add several drops of NaOCl from the original NaOCl bottle to the weighed Erlenmeyer flask, the solution turned to yellow instantaneously
4. Weigh the solution and the Erlenmeyer flask again
5. Immediately titrate the above solution with the standard sodium thiosulfate solution. Record the volume of titrant used.
6. Repeat the whole process several times.

Note: The density of the NaOCl solution needs to be determined before the titration. Deliver a known volume of NaOCl into the preweighed volumetric flask or beaker and then weighing the volumetric flask (or beaker)+ sample.

Data Analysis:

NaOCl concentration (M) is obtained from the following equation:

$$\frac{\text{volume of Na}_2\text{S}_2\text{O}_3 \text{ (ml)} \times 0.001 \left(\frac{\text{l}}{\text{ml}}\right) \times \text{Na}_2\text{S}_2\text{O}_3 \text{ concentration (M)}}{2 \times \frac{\text{weight of NaOCl sample (g)}}{\text{density of NaOCl sample } \left(\frac{\text{g}}{\text{ml}}\right)} \times 0.001 \left(\frac{\text{l}}{\text{ml}}\right)} \quad (\text{G-5})$$

## Appendix G Results of Mercury Absorption in NaOCl-NaCl at Low and Intermediate pH

Total Hg-N<sub>2</sub> flow rate was 1 l/min. The inlet Hg was 97.7 ppb.  $k_{g, \text{Hg}} = 0.39$  mole/s-atm-m<sup>2</sup>,  $k_{l, \text{Hg}^{++}}(25^\circ\text{C}) = 2.2 \times 10^{-5}$  m/s,  $k_{l, \text{Hg}^{++}}(55^\circ\text{C}) = 4.0 \times 10^{-5}$  m/s.

Table G-1 Detailed results of Hg<sup>0</sup> absorption in NaOCl-NaCl at low pH at 25°C, no external HgCl<sub>2</sub> injection,  $[\text{Hg}^{++}]_i = [\text{Hg}^{++}]_{\text{absorbed}} + \frac{N_{\text{Hg}}}{k_{l, \text{Hg}^{++}}}$ .

## Appendix H Using $a_{Cl_2,i}$ for Low pH Results of Hg Absorption in NaOCl-NaCl at 25°C

The bulk chlorine activity is corrected to give interfacial chlorine activity for chlorine desorption and reaction at the gas-liquid interface:

$$k_{l, Cl_2}^o (a_{Cl_2, b} - a_{Cl_2, i}) = k_{g, Cl_2} (H_{Cl_2} a_{Cl_2, i} - 0) + N_{Hg} \quad (H-1)$$

This resulted in:

$$a_{Cl_2, i} = \frac{k_{l, Cl_2}^o a_{Cl_2, b} - N_{Hg}}{k_{g, Cl_2} H_{Cl_2} + k_{l, Cl_2}^o} \quad (H-2)$$

The results are given in table H-1.

Table H-1 Hg absorption in NaOCl-NaCl at low pH (with HCl addition) at 25°C.  $k_{g, Hg} = 0.39$  mole/s-atm-m<sup>2</sup>,  $k_{g, Cl_2} = 0.31$  mole/s-atm-m<sup>2</sup>,  $k_{l, Hg}^{o+} = 2.2 \times 10^{-5}$  m/s,  $k_{l, Cl_2}^o = 2.9 \times 10^{-5}$  m/s. No external HgCl<sub>2</sub> injection. The inlet Hg was 97.7 ppb.

1 M NaCl	63.7	2.3	0.6	6.7E-09	6.4	4.97	1.1	-1.3E-10

\* with 1 M NaCl and 25°C

Although this correction reduced the chlorine activity by  $2 \times 10^3$  M, the results are still underpredicted compared to the high pH results. For higher pH, such as pH = 5, the predicted  $a_{\text{Cl}_{2,i}}$  is a negative value. This is due to the fact that there was little chlorine available in the bulk solution that it was depleted by reaction as soon as it was generated.

## Glossary

- $A$  = gas - liquid contact area ( $\text{m}^2$ )
- $C$  = instantaneous bulk concentration in the liquid (M)
- $C_{\text{Hg}}$  = instantaneous bulk mercury concentration in the liquid (M)
- $C_{\text{Hg, initial}}$  = initial injected  $\text{HgCl}_2$  concentration in the liquid (M)
- $[\text{Cl}_2]_{\text{b}}$  =  $\text{Cl}_2$  concentration in the bulk liquid (M)
- $[\text{Cl}_2]_{\text{i}}$  =  $\text{Cl}_2$  concentration at the liquid side interface (M)
- $[\text{Cr}_2\text{O}_7^{=}]_{\text{b}}$  =  $\text{Cr}_2\text{O}_7^{=}$  concentration in the bulk liquid (M)
- $[\text{Cr}_2\text{O}_7^{=}]_{\text{i}}$  =  $\text{Cr}_2\text{O}_7^{=}$  concentration at the liquid side interface (M)
- $D_{\text{CO}_2\text{-H}_2\text{O}}$  = diffusion coefficient of  $\text{CO}_2$  in water ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{Hg-H}_2\text{O}}$  = diffusion coefficient of Hg in water ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{Hg}^{++}\text{-H}_2\text{O}}$  = diffusion coefficient of  $\text{Hg}^{++}$  in water ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{Hg(g)-Air}}$  = interdiffusion coefficient of Hg and air ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{Hg(g)-N}_2}$  = interdiffusion coefficient of Hg and  $\text{N}_2$  ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{MnO}_4^- \text{- H}_2\text{O}}$  = liquid film diffusion coefficient of  $\text{MnO}_4^-$  ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{SO}_2\text{- H}_2\text{O}}$  = liquid film diffusion coefficient of  $\text{SO}_2$  ( $\text{m}^2 \text{s}^{-1}$ )
- $D_{\text{SO}_2\text{- N}_2}$  = interdiffusion coefficient of  $\text{SO}_2$  and  $\text{N}_2$  ( $\text{m}^2 \text{s}^{-1}$ )
- $G$  = gas flow rate ( $\text{l min}^{-1}$ )
- $[\text{H}_2\text{O}_2]_{\text{b}}$  = hydrogen peroxide concentration in the bulk liquid (M)
- $[\text{H}_2\text{O}_2]_{\text{i}}$  = hydrogen peroxide concentration at the liquid side interface (M)
- $H_{\text{Hg}}$  = Henry's constant of Hg ( $\text{atm M}^{-1}$ )
- $[\text{Hg(II)}]_{\text{absorbed}}$  = bulk liquid  $\text{Hg(II)}$  conc. that absorbed from gas phase (M)

$[Hg(II)]_b$  = Hg(II) concentration in the bulk liquid (M)

$[Hg(II)]_i$  = Hg(II) concentration at the liquid side interface (M)

$K_1$  or  $K_2$  = equilibrium constant

$k_1$  = first order rate constant ( $s^{-1}$ )

$k_2$  = second order rate constant ( $M^{-1} s^{-1}$ )

$k_3$  = third order rate constant ( $M^{-2} s^{-1}$ )

$k_3'$  = third order rate constant defined by equation (6-29) ( $M^{-2} s^{-1}$ )

$k_g$  = gas film mass transfer coefficient ( $\text{mole } s^{-1} \text{ atm}^{-1} \text{ m}^{-2}$ )

$K_g'$  = normalized Hg flux,  $\frac{N_{Hg}}{P_{Hgi}}$  ( $\text{mole } s^{-1} \text{ atm}^{-1} \text{ m}^{-2}$ )

$k_{l, Hg}^o$  = physical liquid film mass transfer coefficient of Hg ( $m s^{-1}$ )

$k_{l, Hg^{++}}^o$  = physical liquid film mass transfer coefficient of  $Hg^{++}$  ( $m s^{-1}$ )

$k_{l, MnO_4^-}^o$  = physical liquid film mass transfer coefficient of  $MnO_4^-$  ( $m s^{-1}$ )

$k_{l, SO_2}^o$  = physical liquid phase mass transfer coefficient of  $SO_2$  ( $m s^{-1}$ )

$[Mn(II)]_b$  = Mn(II) concentration in the bulk liquid (M)

$[Mn(II)]_i$  = Mn(II) concentration at the liquid side interface (M)

$[MnO_4^-]_b$  = permanganate concentration in the bulk liquid (M)

$[MnO_4^-]_i$  = permanganate concentration at the liquid side interface (M)

$[Na_2S]_b$  =  $Na_2S$  concentration in the bulk liquid (M)

$n_g$  = gas phase agitation speed (rpm)

$n_l$  = liquid phase agitation speed (rpm)

$N_{Hg}$  = Hg flux ( $\text{mole } s^{-1} \text{ m}^{-2}$ )

$P_{CO_2, out}$  = outlet  $CO_2$  partial pressure (atm)

$P_{Hgb}$  = partial pressure of Hg in the bulk gas phase (atm)

$P_{Hgi}$  = partial pressure of Hg at the gas side interface (atm)

$P_{\text{Hg, in}}$  = partial pressure of Hg in the inlet gas (atm)

$P_{\text{Hg, out}}$  = partial pressure of Hg in the outlet gas (atm)

$R$  = gas constant,  $8.314 \frac{\text{Pa m}^3}{\text{mole } ^\circ\text{K}}$

$t$  = time (s)

$T$  = temperature ( $^\circ\text{K}$ )

$V$  = volume of the liquid solution ( $\text{m}^3$ )

$x$  = distance measured from the gas-liquid interface (m)

$a_{\text{Cl}^-}$  = activity of  $\text{Cl}^-$  (M)

$a_{\text{Cl}_2}$  = activity of aqueous  $\text{Cl}_2$  (M)

$a_{\text{H}^+}$  = activity of  $\text{H}^+$  (M)

$a_{\text{HOCl}}$  = activity of  $\text{HOCl}$  (M)

$a_{\text{OCl}^-}$  = activity of  $\text{OCl}^-$  (M)

$\gamma_{\text{Cl}^-}$  = activity coefficient of  $\text{Cl}^-$

$\gamma_{\text{Cl}_2}$  = activity coefficient of aqueous  $\text{Cl}_2$

$\gamma_{\text{HOCl}}$  = activity coefficient of  $\text{HOCl}$

$\gamma_{\text{Na}^+}$  = activity coefficient of  $\text{Na}^+$

$\gamma_{\text{NaCl}}$  = activity coefficient of  $\text{NaCl}$

$\gamma_{\text{OCl}^-}$  = activity coefficient of  $\text{OCl}^-$

## **Vita**

Lingbing Zhao was born in Zhejiang, China on June 7, 1969, the youngest daughter of Qijin Zuo and Wanxian Zhao. After graduating from Taizhou High School in 1986, she entered Zhejiang University in September of that year and earned the degree of Bachelor of Science in Chemical Engineering in July, 1990. From 1990 to 1992, she attended the graduate school at East China University of Chemical Technology in Shanghai, China. She transferred to the University of Texas at Austin in September, 1992 and received Master of Science in Chemical Engineering in May, 1996. She worked part time for Radian International in Austin, Texas during the Summer and Fall of 1994. Employment has been accepted with Exxon Chemical Company in Baytown, TX.
